In a decision that seems to have been reached amid some concern about the politicisation of international non-governmental scientific organisations, the Council of the IUGG at an extraordinary meeting held in Durham has voted 47–7 to cancel the membership of Taiwan and to bring in the People's Republic of China. The vote is particularly important because it could open the way to much wider Chinese membership of international organisations, though presumably only at the price of much wider expulsion of Taiwan.

Last year the International Union of Geological Science meeting in Australia took a similar course, but the Australian government had not allowed Taiwanese representatives entry visas to state their case. In Durham Professor Y. B. Tsai spoke for Taiwan, but returned with a colleague to Taipei after the ratification of the decision, even though he was scheduled to speak at a subsequent scientific meeting.

The ballot was secret but there is no doubt that the UK and United States voted against. Both these countries stressed that they had no opposition at all to Peking's membership, but only to the preconditions. Indeed, the UK tried without success to get a motion considered which simply admitted Peking whilst taking no action on Taipei. In the event it was clear that many representatives had come with the firmest instructions from their governments or academies to admit Peking on its own terms. A few countries did not even send a scientist to vote for them but despatched an embassy official from London—a practice which the International Council of Scientific Unions would do well to look at as soon as possible.

In hindsight the haste with which the IUGG seems to have brought the matter to a head was probably unnecessary. The next IUGG assembly is planned for Australia in 1979 and it was thought at one time that Australia would refuse to support a meeting at which Taipei but not Peking was represented. But the Australian position has since softened somewhat and it is possible that the Taiwanese would have been admitted provided they did not claim to be official representatives.

The Taiwan position is difficult now, in spite of assurances that the Bureau of the IUGG will look after the interests of individuals and will ensure that appropriate information gets through. Many Durham delegates urged the Taiwanese to stay, to continue to attend meetings and to remain in the closest touch. But there is a political reason why this is unlikely. The motion that was passed did not simply call for a switch of membership —it pointedly went out of its way to explain the reason. that the "vast majority of countries" now recognise Taiwan to be a province of the People's Republic of China. The Taiwan government also claims that Taiwan is a province of China—but not, of course of the People's Republic. And the Academia Sinica of Taipei is on record as having claimed to speak only for scientists within its own shores. Thus any organisation which acknowledges *de jure* Peking rule over Taipei is unlikely to see Taiwanese citizens at its meetings in the forseeable future.

The whole sad affair, which gives the impression of having been pushed through for political convenience, will undoubtedly give people ideas about getting rid of other countries because their policies are disagreeable or their political base is weak. □

SWEDEN

Spending a packet

Wendy Barnaby reports from Stockholm on one aspect of Sweden's continuing nuclear debate

Last March, the Swedish branch of the Friends of the Earth sent a letter to the Prime Minister complaining that a so-called study packet on energy, produced with government funds, was in fact propaganda for nuclear power. The letter provoked some interest. The state auditors delved a little into the financing of the agency distributing the packet, Centrala Driftledningen (CDL), a non profit-making body which promotes many-sided cooperation between the electricity companies, and which is half financed by the State Power Board. The Prime Minister, Thorbjörn Fälldin, replied that he had not known about the distribution of the packet, but that to control the agency's operations would conflict with democratic principles. A question was asked in parliament, but received only a vague answer from the Energy Minister. Then recently—just before the government was to approve the State Power Board's annual budget—rumours circulated that its normal contribution of about $865,000 to CDL would be axed. In the event, the money was approved and the agency will be able to continue its normal operations.

The study packet was written by CDL and various organisations responsible for energy supplies. Meant for schools, study circles, trade unions, companies and so on, it consists of seven attractive booklets totalling 152 pages, as well as a 102-page book entitled *Nuclear Energy: Principles and Problems* written by a reactor physicist who works with the Atomic Energy Company. Describing the aims of the package, the distributors said that its facts should be correct and easily distinguishable from evaluations.

In some cases, this holds; often it does not. One of the booklets stresses, for example, that no increase in genetic defects has been found in the offspring of survivors of Hiroshima and Nagasaki. But for a public generally ignorant of the studies showing that the survivors have more than their share of medical complaints, the suspicion arises that the authors are trying to minimise the effects of radiation. The same booklet also asserts that the risks of nuclear reactors are small, that the industry is subjected to stricter control than any other, and that the dangers of nuclear-weapon proliferation and terrorism have been exaggerated. In short, the publications, taken together, leave no doubt that the best available energy source is nuclear.

Following the news that CDL would be able to continue, its director, Bengt Sterne, commented: "It was a political question—it's all over now". Of course it *was* a political question. The President of Friends of the Earth, Lennart Daléus, agrees in principle that CDL should have its money, but says that, as it is the only organisation with enough money to give the public significant amounts of information, it should use government funds more responsibly. Certainly, the problem would be eased if both sides of the nuclear debate could compete on equal terms. It has long been a sore point with antinuclear groups that government support is so one-sided. A spokesman at the Department of Industry, which also deals with energy, says that at the moment there is no government funding of anti-nuclear groups—although there is about $100,000 in the pipeline for them. A proposal by the Liberal Party that they should get an annual grant of about $22,000 seems to have been dropped. Even if it had been adopted, total government spending would still have favoured the pro-nuclear groups by about eleven to one. □

NETHERLANDS

●Mrs Vorrink, Holland's Minister of Public Health and Environmental Protection, plans to eliminate the presence of phosphates in detergents by 1985, according to a report just published by the ministry and already agreed upon in a coordination-committee in which all departments take part. Partial or regional bans operate in Canada and the US; Germany plans to cut back the phosphate content in detergents to half the present level.

The problem is international, and in each country is caused partly by pollution from abroad. In the Netherlands more than half of the phosphates in the surface-waters is imported from other countries, and of the rest a good portion comes from detergents. The initiative to ban phosphates will help, but a more complete solution would require European action. Industry's assistance would also be necessary.

Before Mrs Vorrink reached the end of her ministerial appointment—she is unlikely to return in the new government now in the process of formation—she concerned herself with the warning on spray cans which contain halocarbons. The warning mentions that they can have deleterious environmental effects. The minister's memorandum announces a ban on the use of the gases in spray cans. Industry protested immediately, saying that work for 700 people would be in danger and that the measures would be premature, as no scientific evidence was available that the ozone layer is broken down by halocarbons.

●The former Minister for Science Policy, Mr Trip, will not be part of a new government. What is more, his portfolio is said to be in danger, in spite of advice to the Prime Minister, Mr den Uyl. He has received two reports on improving the communication of information on science and technology to a larger public. One was compiled by two committees, in which scientists, science-information officers and science writers participated.

The product of 18 months' work, the report concluded that a central service for information on science should be created at the Royal Academy of Sciences, which should have a coordinating role. In the Netherlands all universities have their press- and information-offices; so too do most of the government research institutes. The position has improved in recent years, but gaps remain. Information is restricted mainly to the institutes' research, and no connection exists with research work elsewhere. The new service has to work as independently as possible and aims at objectivity.

With so many groups working in this area in the Netherlands already, Mr Trip formed another committee to examine whether the government should subsidise existing activities, particularly of foundations which promoted information based on a particular view on society. The committee considered that critical evaluations of the development of science and technology were necessary, and the minister says in his recommendations that more participatory forms of discussion on science are needed, involving various organisations and groups in society. The committee recommends that government money be used for this, without offering criteria for its disbursement. Thus a 'Science for Citizens' programme which is already carried out on a modest scale in the Netherlands may now grow larger.

●Alternative forms of energy receive much attention in this most densely populated country in the world. After all, nuclear power is not very popular: the construction of three 1,000 MW power plants, and the extension of the ultracentrifuge uranium enrichment plant at Almelo which is part of the tripartite consortium with Britain and Germany, form one of the points of discussion about the formation of a new government. Nuclear matters still dominate research, but alternative energies may obtain a foothold. The minister who has energy in his portfolio, Mr Lubbers of Economic Affairs, is a proponent of nuclear energy on what he calls a modest scale. He has put into service an experimental wind turbine, part of a five-year 15-million-guilder national research programme on wind energy.

The experimental wind turbine, 5 m in diameter, is of the Darreus-type and was built by Fokker-VFW as a spin-off of the rotorblade-production for helicopters. If it is successful a wind turbine 25 m in diameter will be built as well as a more classic wind-turbine of the same size. Mr Lubbers sees only a restricted role for wind energy, however, especially with the environmental and country-planning problems. Experts expect more than 10–20% of future electricity production to come from the wind.

The problem seems even greater with solar energy, but in fact some 50 houses with solar collectors and other energy saving devices have been built in Holland during the last three years. An ecological group, 'De Kleine Aarde' (the small-scale world), began with a recycling house five years ago and the reseach of a professor at Eindhoven Technical University who lives with his family in a solar house was a stimulus. Philips is doing experiments on 32 houses with collectors; an office building will be constucted with collectors; and this month four houses have been finished in which technical collaborators of the national research organisation will live with their instruments.

The research centre for the building industry foresees the introduction of solar energy devices in houses for space heating and production of warm water from 1980. A national symposium will be held next month on the development of solar energy in the Netherlands.

Casper Schuuring

IN BRIEF

SA nuclear alarm

The question mark surrounding the development of South Africa's capacity to produce nuclear weapons was brought more fully into relief last week following allegations made by the Soviet news agency Tass that South Africa was preparing to carry out weapons tests. The allegations anticipated the rush of diplomatic moves over Southern Africa late last week, and Dr Owen, the UK Foreign Secretary, and Herr Genscher, West Germany's Foreign Minister, each brought the subject up with their South African counterpart, Mr Pik Botha.

Bonn this week denied more reports of collaboration with South Africa on nuclear development. Like allegations earlier this year relating to contacts on nuclear matters between the two countries, these were based on documents reportedly in the possession of the African National Congress, the exiled black nationalist organisation based in Lusaka. According to the *Observer*, the ANC says that many military visits to Germany have been made under the cover of the South African Council for Scientific and Industrial Research, and are arranged through the scientific counsellor at the Bonn Embassy. ANC officials are also reported as saying that 15 German research institutions, including the Max Planck Institute for Nuclear Physics at Heidelberg, have contributed to South Africa's arms programme.

Committee's report

In its latest report, the UK Select Committee on Science and Technology has examined a particular instance in which British industry did not exploit a potentially useful innovation. Called 'A case study of machine tool development at the Cranfield Institute of Technology', the report outlines how a high-precision electronic formed-wheel gear-grinding machine, developed at Cranfield Unit for Precision Engineering and Matrix Machine Tools Ltd, failed to gain the financial support needed to develop it commercially.

Blame for this failure is distributed among most of those concerned with the project, though the committee admits that no one acted totally unreasonably. It criticises the Department of Industry's Mechanical Engineering and Machine Tools Requirements Board for not seeking more evidence on the machine's potential market; and the industries involved are criticised for not considering developing the machine as a joint venture.

Berkeley women

THOMAS H. JUKES

THE University of California at Berkeley has long prided itself as being a citadel where liberal causes and freedom of thought, action and expression were fostered. Fostered, that is, by a predominantly male faculty. Women did the typing. A less-publicised aspect of campus life at Berkeley is that many women students feel personally insecure. These circumstances lend unusual interest to the appearance of a report, *Women Students at Berkeley: Views and Data on Possible Sex Discrimination in Academic Programs,* that has just been issued by the Office of the Chancellor; 140 pages long, it contains excerpts from academic units' self-evaluation reports and from students' responses to questionnaires.

Chairmen of departments, and other male administrators, made responses that were in many cases masterpieces of low-key diplomacy. The devotion of some respondents to women's liberation was exceeded only by the complete, or nearly complete, absence of women from regular faculty appointments in their departments. Most of us are familiar with the pre-emption of certain scientific fields, such as engineering, by males. It is also evident that physics, chemistry, astronomy and mathematics are predominantly male worlds, in which barriers against women are apparently raised long before college age. However, it surprised me to learn that "Palaeontology is simply a field of endeavour that fewer women than men find attractive, and it is naive to believe that the current disparity in numbers of women to men in the field can be brought to parity by governmental fiat".

Space permits only a few highlights. The Chairman of the Department of Dramatic Arts notes that "Drama, for 2,000 years, has been predominantly written and acted by males . . . Hamlet is a better role than Gertrude, and there are over 30 men and two women in the cast". It might be retorted that Portia, in *The Merchant of Venice,* was much better at making up her mind and getting results than was the moody and vacillating Dane. Also, transvestite males filled women's roles on the stage of Shakespeare's day. Why should not the reverse procedure be tried now?

A laboratory director says, "In all fairness, it must be pointed out that the natural environmental conditions at the High Altitude Laboratories are physiologically stressful, and for whatever the underlying sociological reasons, the use of the facilities by men has been substantially greater than by women". We hope that his laboratory will provide experimental evidence for the interesting implication that females are more affected by anoxia than are males. I believe that experimental subjects could readily be obtained, for US Governmental Affirmative Action policies have brought many female rangers to the National Parks and Forest Service areas close to the High Altitude Research Laboratory. I have encountered these athletic young females striding along the trails at elevations above 11,000 feet, apparently without signs of stress. Also, women members of the American Alpine Club are more tolerant of high altitudes than they are of suggestions that they are less able than males to adapt to them.

Medicine is a famous battleground of the sexes, and the early women MDs are revered as much as freedom fighters as for their clinical prowess. As every medical student knows, many professors in the clinical sciences are masterful male chauvinists. The report contains several citations of this, and also the following gem: "A neurologist described the Argyll-Robertson pupil 'like a whore who accommodates but does not react' ".

Forty-six of the fifty-six female students responding to the questionnaire expressed fear of being raped on the campus at night. Practically none of their professors even mentioned this problem.

news and views

Optimal foraging: theory and experiment

from John Krebs

It may seem a bit optimistic to try and predict in theory how an optimally efficient predator ought to behave, and then expect the predictions of the model to work. Nevertheless a growing body of experiment indicates that the decision rules used by predators are often surprisingly close to those predicted by simple models.

The idea of trying to formulate decision rules for optimally efficient predators was suggested 11 years ago by R. H. MacArthur and E. R. Pianka (*Am. Nat.* **100** 603; 1966) who proposed that predators (using this term in a very broad sense) are designed by natural selection to maximise their net rate of food intake while foraging. They discussed in these terms how an ideal predator might make choices about which food items to eat and where to forage. E. L. Charnov, J. M. Emlen and T. W. Schoener are among several theoreticians who have followed up MacArthur's and Pianka's ideas, and experimental work designed to test the theory has been done, mainly in the laboratory, with birds, arthropods and fish.

Imagine a bird faced with a variety of seeds of different sizes. Ignoring for the moment considerations such as taste and presence or absence of trace nutrients, an optimally efficient bird ought to be capable of ranking the seed types in terms of profitability – the net quantity of food extracted per second of handling time – and when given a straight choice it should prefer the most profitable seeds. There are several studies which have confirmed this basic assumption of optimal diet models for a variety of predators. The predictions of the models relate the extent to which the predator should select only profitable prey and the rate of encounter with the various prey types. In general, predators should be more selective when profitable prey are encountered frequently than when they are rare. (Note that the term 'encounter rate' covers the effects of camouflage and so on.) This makes intuitive sense. When the predator pauses to handle an unprofitable item, it uses up time which could otherwise be spent in travelling on to the next prey. If profitable prey are sufficiently common it will always be economically advantageous to pass over the less profitable prey. On the other hand in a time of shortage even unprofitable prey may boost the predator's average rate of intake. More precisely, the rule for optimal choice of food items is that the predator should add a new prey type to its diet only if the net food yield per second of handling time (E/h) for this prey type exceeds the predator's current overall net rate of food intake. This prediction can be tested quantitatively by measuring the food values (usually considered in terms of weight or energy), handling times, and encounter rates with various prey types. Particularly noteworthy is the prediction that a predator's decision to accept or reject a new prey type ought to depend only on the value of E/h for the new prey and not on the encounter rate. In other words, there should be (exactly specifiable) conditions in which a predator ignores very common, unprofitable prey.

The importance of this last point can be seen by referring to an experimental test of optimal diet theory in which Werner and Hall (*Ecology* **55**, 1042; 1974) examined the selection of different sizes of *Daphnia* by bluegill sunfish (*Lepomis macrochirus*). Werner and Hall allowed small groups of sunfish to forage in a large tank containing a known mixture of *Daphnia* of varying sizes. They estimated the encounter rate with each size class by making some simple assumptions about the visual field of the fish, and were then able to predict the optimal contents of the sunfishes' diet on the basis of the relative profitability of different sized prey. Large *Daphnia* are more profitable than smaller ones because they contain more food but take no longer to handle. Werner and Hall found that when all size classes were available at a low density the fish were totally non-selective, but when the density of all size classes was increased, the fish selectively ignored small *Daphnia*. This switch in behaviour occurred at the encounter rate with large *Daphnia* predicted by the optimal diet model.

More recently O'Brien *et al.* (*Ecology* **57**, 1304; 1976) have pointed out that Werner's and Hall's results could equally well be explained by assuming that the fish obey the rule of always taking the *Daphnia* with the largest apparent size (a small *Daphnia* close by might appear larger than a big one at a distance). O'Brien *et al.* showed that sunfish do in fact take the apparently larger of the two *Daphnia* in a simultaneous choice experiment, and they incorporated these results into a simulation model which predicted a change from non-selective predation at the encounter rate observed by Werner and Hall.

O'Brien *et al.* view their results as demonstrating a proximate rule by which the sunfish achieve the ultimate goal of optimal foraging, but this may be incorrect. The 'take the largest' rule, in agreement with the optimal diet model, predicts that the fish should become more selective as the density of large *Daphnia* is increased, but the two models differ in their prediction of what ought to happen if now the density of small prey is increased enormously. The optimal diet model says that the fish ought to continue to ignore small *Daphnia* even when they are much commoner than large prey, as long as the density of large prey is above the selection threshold. In contrast, the 'take the largest' rule predicts that as the small prey become more abundant, they are more likely to appear larger than big prey to the fish, and hence be selected.

Werner and Hall did not do the test which would enable one to decide

---

John Krebs is a lecturer in Zoology at the Edward Grey Institute of Field Ornithology in the University of Oxford.

whether sunfish use the 'take the largest' rule, or the optimal diet rule. Two more recent studies have, however, shown that two species of bird will ignore very abundant but unprofitable prey when the encounter rate with profitable sizes is above the predicted level. Goss Custard (*Anim. Behav.* **25**, 10; 1977) showed this with redshank hunting for polychaete worms and Krebs *et al.* (*Anim. Behav.* **15**, 30; 1977) obtained similar results with captive great tits feeding on pieces of mealworm cut into different sizes.

Charnov (*Theor. Pop. Biol.* **9**, 129; 1976) J. M. Emlen (*Ecology; an evolutionary approach* Addison-Wesley, Reading, Massachusetts, 1973), Cook and Hubbard (*J. Anim. Ecol.* **46**, 115; 1977), and Parker and Stuart (*Am. Nat.* **110**, 1055; 1976) are prominent among those who have developed models for optimal allocation of time by a predator to different patches of prey. The models assume that when a predator arrives in a new patch or clump of prey (which might, for example, be a bush laden with berries) its food intake is at first high, but soon declines as the food patch is depleted. The optimal predator should leave a patch when its net rate of food intake within the patch drops to a level equal to the expected intake from the rest of the area. This latter quantity depends on both the average quality of patches and the time and energy cost of travelling between patches. (It is a weakness of both this and the optimal diet models that nothing is specified about how the predator acquires information about its average rate of intake.)

The most straightforward predictions of the model are as follows. First, if patch quality is held constant, the time spent foraging in each patch should depend on the cost of travelling between patches. The exact relationship between inter-patch travel time and time spent foraging in each patch can be predicted by measuring the curve of food intake as a function of foraging time in a patch. This has been done by Cowie (*Nature* **268**, 137; 1977) using captive great tits foraging for mealworms in sawdust-filled pots. Cowie's results show not only that the time spent in a patch is related to travel time in the way predicted by the model, but that data give a closer fit to the model if one considers net energy intake (subtracting the energy cost of travelling) rather than gross intake. The second testable prediction is that if travel time is held constant and patch quality is varied, the predator should leave each patch within an area at the same threshold rate of food intake, regardless of the initial quality of the patch. This prediction has also been tested and confirmed in laboratory experiments with birds (Krebs *et al.* *Anim. Behav.* **22**, 953; 1974).

In conclusion, although optimal foraging models are in many ways grossly oversimplified, they are good descriptions of the decision rules used by predators in simple laboratory and field conditions. There are many ways in which the models could be elaborated and made more realistic, for example by dealing with the problem of how a predator samples a changing environment in order to assess its average rate of food intake, and how the qualitative differences in food types influence its choice of an optimal diet. □

Cosmic ray composition at high energies

rom a Correspondent

THE mass composition of primary cosmic ray particles above an energy of $\sim 10^{12}$ eV still remains something of a mystery. At around 10^{11} eV per nucleon very detailed isotopic measurements have now been made, but from 10^{12} eV right up to the highest detected energies of $\sim 10^{20}$ eV per particle controversial debate still rages as to even the simplest question of the proportion of protons in the primary flux. This uncertainty does not reflect any lack of interest or experimental effort attached to the problem as the mass composition has very direct bearing on the origin of cosmic rays, a still very open question. The low primary flux and the Earth's atmosphere combine to make experimental investigation very difficult.

It has long been recognised that at $\sim 10^{11}$ eV $\sim 90\%$ of the primary flux is protons, $\sim 10\%$ α particles and $\sim 1\%$ the rest, largely reflecting the accepted Universal abundance. At $\sim 10^{12}$ eV early satellite experiments by Grigorov *et al.* (*Proc. 12th Int. Conf. on Cosmic Rays* **5**, 1746; 1971) using ionisation calorimeters suggested that the proportion of protons dropped with increasing energy. However the general assumption has usually been that the composition at least up to $\sim 10^{14}$ eV is not too different from that measured at lower energies.

A recent paper by Adair *et al.* (*Phys. Rev. Lett.* **39**, 112; 1977) seems however to support Grigorov's suggestion. This new work is concerned with information deduced from the charge ratio of secondary cosmic ray muons measured at sea level. Muons reach sea level as the decay products of π mesons and K mesons produced high in the atmosphere from interactions of cosmic ray hadrons with air nuclei. As the primary cosmic rays start off carrying a net positive charge, this is reflected in the excess of positively charged muons at sea level.

Experimentally the cosmic ray sea level muon charge ratio (μ^+/μ^-) is a slow function of sea level muon energy, rising from ~ 1.2 at 10^9 eV to ~ 1.3 at 10^{12} eV. In recent years a number of theoretical attempts have been made to explain this ratio in terms of the known composition of the primary flux and the details of the hadron-hadron interactions. Earlier this year a group from NASA, Badwher *et al.* (*Phys. Rev.* **D15**, 820; 1977), calculated the sea level differential muon momentum spectrum and charge ratio from 1 GeV/c to 5,000 GeV/c, using available accelerator data. They found excellent agreement between their calculations and existing experimental data and had no need to invoke any change either in the cosmic ray chemical composition or in the nature of the hadron–nucleus interaction at hadron energies above 1.5×10^{12} eV. This result was clearly in contradiction to some earlier conclusions of Adair (*Phys. Rev. Lett.* **33**, 115; 1974).

In view of this discrepancy Adair and his collleagues have now taken the research one stage further by investigating the problem experimentally in the laboratory by observing the charge ratio of muons produced by the interaction of the primary cosmic ray nucleons with the thick atmosphere. The experiment was conducted at Fermilab using the interaction of 400 GeV protons with thick copper targets.

In general, measurements of the charge ratio of muons produced at different energies were made by determining the intensities of positive and negative muons produced by the interaction of 400 GeV protons with copper targets of different mean densities. The charge of the muons was determined by magnetic analysis and the muon energies were measured by determining their range through steel and earth absorbers. For a very dense target the intensity of muons from meson decay is greatly suppressed relative to the atmosphere as a target and sources of muons which do not scale with density cannot be neglected. Such contamination was corrected for by use of targets of differing mean densities. The experiments produced a measured charge ratio for muons of 1.66 ± 0.09.

These measurements enabled Adair *et al.* to deduce from the cosmic ray energy spectrum that a muon charge ratio of 1.50 ± 0.08 should be obtained at sea level for cosmic ray muons of energy $>10^{11}$ eV assuming the accepted primary mass composition. This charge ratio value is significantly higher than the actual measured value at sea level of 1.30. This actual value indicates therefore that ~25% of the total primary nucleon flux must be made up of neutrons. (The primary nucleon flux includes all nucleons whether in multi-nucleon nuclei or not). In other words the flux of heavy nuclei in primary cosmic rays at energies $\gtrsim 10^{12}$ eV per nucleon must be larger than that observed at lower energies.

So this conclusion supports the earlier suggestion from the satellite work of Grigorov *et al*. Such a conclusion if confirmed will be of the utmost importance to cosmic ray physicists. ☐

Ribsomal switches

from E. G. Richards

THE notion that RNA molecules can exist in several metastable conformational states and that such conformers can be separated by electrophoresis on polyacrylamide gels is by now well known. It all began with tRNA; 5S RNA was the next to exhibit this property and more recently, 16S RNA has been observed to do the same. So far the transformation from one conformer to another has required heat or reagents such as magnesium ions or EDTA. The idea that proteins could do this has remained speculative though proteins have been described that destabilise double helical regions in RNA structures.

These speculations have recently been turned into demonstrations in a paper by Hochkeppel and Craven (*J. molec. Biol.* **113,** 623; 1977). It had previously been shown that 16S RNA isolated from the 30S ribosomal subunits of *Escherichia coli* by treatment with phenol (16S RNA^{p}) was not the same as the RNA isolated by treatment with acetic acid and urea (16S RNA^{a}): the two forms can be separated by electrophoresis in agarose/polyacrylamide and 16S RNA^{a} bound ribosomal proteins that 16S RNA^{p} did not. In their latest paper they show that if they bind several of the ribosomal proteins to 16S RNA^{p}, and then remove them again, there results RNA migrating with a mobility close to that of the slower 16S RNA^{a} rather than that of the faster moving 16S RNA^{p}. Appropriate controls established that it was not the re-extraction procedure itself that wrought this change. Proteins found to have this effect were S4, S7 and S8, but this of course does not preclude that other untried ones do the same.

These authors went on to demonstrate in a similar way that 16S RNA^{p} pretreated with S7 (the protein being bound to the RNA and then removed) was able to bind S9 whereas untreated 16S RNA^{p} was not. 16S RNA^{p} pretreated with both S4 and S7 was even more efficient at binding S9 but pretreatment with S4 alone did not affect the capacity to bind S9 even though it resulted in a lowered mobility. It would therefore seem that the different ribosomal proteins are able to bring about several different conformational states, with differential protein binding ability but all with reduced mobility.

Further experiments demonstrated that the RNA extracted from the reconstitution intermediate (RI) migrated slowly like 16S RNA^{a} while that extracted from the heat activated particle (RI*) migrated with the faster mobility. It was similarly shown that inactivation by ion depletion of intact 30S ribosomal subunits results in the extraction of RNA with a lowered mobility as well as a loss of capacity to bind tRNA in the intact particle.

Present understanding suggests that the difference between one RNA conformer and another must reside either in the pattern of base-paired helical regions constituting the secondary structure or in the pattern of folding and interaction deployed in the tertiary structure. It thus seems likely that to change one conformer into another, base pairs or tertiary interactions must first be undone. Several proteins are able to bring this about (including the ribosomal protein S1) so it is not too surprising that the ribosomal proteins, S4, S7 and S8 can do likewise. Nevertheless, the implications for the study of ribosomes are very interesting indeed.

As Hochkeppel and Craven themselves point out, it is now possible to begin to give a rational interpretation in terms of conformational changes in the RNA of the assembly maps presented by Mizushima and Nomura. One can envisage a series of conformational switches each turned on by the binding of a specific protein and each enabling the next protein to bind. If this speculation turns out to be valid, the assembly of a ribosome must be seen as a carefully orchestrated process rather than a series of random associations occurring in no fixed sequence.

The possible importance of conformational switches was discussed a few months ago by Weidner *et al.* (*Nature* **266,** 193; 1977) in a discussion of the possible conformational states of 5S RNA, another ribosomal component. Recently Bear *et al.* (*Nucleic Acids Res.* **4,** 2511; 1977) have presented some evidence that the binding of proteins L18 and L25 to 5S RNA wreaks a change in the RNA conformation. The evidence is based on changes on the circular dichroism spectra and melting curves of the RNA and RNA–protein complexes and is not wholely conclusive. It does, however, nudge one's prejudices a little further along the direction of supposing that conformational switches may be an important and widely used trick employed in a variety of dynamic molecular processes in living cells. ☐

New sulphide mineral discovered

from Peter J. Smith

A PREVIOUSLY unknown potassium-rich sulphide mineral has been found by Clarke *et al.* (*Earth planet Sci. Lett.*, **35,** 421; 1977) within a clinopyroxene–ilmenite intergrowth from kimberlite diatremes in South Africa. Until the new sulphide has been more thoroughly investigated, Clarke and his colleagues in Canada and Scotland refrain from giving it a name, referring to it for the time being simply as FSKS (Frank Smith K-sulphide) after the Cape Province diamond mine of which the diatremes form the base. The discovery of a new mineral is not, of course, a completely unheard of event even at this late stage in the development of geology; but what makes FSKS of more than passing interest is that it may indicate an important source of potassium in the upper mantle and throw some light on the vexed question of the transfer of potassium and sulphur from the mantle to the core.

FSKS occurs as ovoid blebs (which also contain pyrrhotite and pentlandite), both as individual grains in cracks in the host clinopyroxene and, more commonly, in close association with the ilmenite lamellae. Because of its high potassium content (8.12–13.01 weight %) it inevitably invites comparison with other potassium-bearing sulphides, namely, the djerfisherite found in several meteorites, the more copper-rich djerfisherite found in the Talnakh copper deposit in Russia, and the rasvumite found in the Russian Khobina massif. But chemical analysis shows FSKS to be quite different from

---

Peter J. Smith is a reader in the Department of Earth Sciences at the Open University.

these minerals. Whereas in djerfisherite the copper contents range from 4–16% and nickel values do not exceed 4%, FSKS contains only 1–3% copper but 11–15% nickel. Moreover, it plots quite distinctly on K–Ni–Fe and K–Cu–Ni ternary diagrams not only from djerfisherite but also from rasvumite.

There seems little doubt, therefore, that FSKS is chemically distinct from other known potassium-rich sulphides. With its primitive cubic unit cell (dimension 10.29 ± 0.03 Å it is also structurally different from rasvumite, which is orthorhombic (although djerfisherite is cubic in structure). What is less certain, however, is whether or not the significance of FSKS extends beyond the particular circumstances represented by the diatremes within which the mineral is found.

Clarke and his coworkers tentatively propose three possible origins for the clinopyroxene – ilmenite – pyrrhotite – pentlandite–FSKS assemblage, whilst admitting that none is consistent with all the observations. According to the first, the clinopyroxene–ilmenite intergrowth would have grown directly from a silicate melt in the mantle and the polysulphide blebs would have been trapped as immiscible liquid droplets. The unmixing of the blebs into the three distinct phases would then probably have taken place below 600 °C, after the material had been transported to the crust in a kimberlitic fluid. And according to the second, all phases, including the ilmenite, would have been unmixed from an initially homogeneous clinopyroxene by a process of multiple exsolution, although again the separation into the three sulphide phases would have had to have taken place after emplacement in the crust. In both of these models it is implicit that the potassium was present in the initial phases. The existence of FSKS in cracks in the host clinopyroxene, however, suggests the addition of potassium at a late stage, presumably within the diatremes themselves. It is thus possible to envisage a third mechanism in which potassium-bearing sulphides are formed metasomatically at low pressure at the expense of earlier sulphide phases.

If the production of FSKS is really dependent upon diatremes, or on the Frank Smith diatremes in particular, the new mineral clearly has little relevance to the general problem of potassium in the mantle and core. This may indeed be the case, for FSKS has a chemical inhomogeneity great enough to be regarded as uncharacteristic of a phase which has been equilibrated in the mantle for long periods, suggesting that it may be a metastable material associated with processes occurring during the rise of kimberlitic fluid to the surface. On the other hand, if, as in the first two models proposed by Clarke *et al.*, FSKS is a primary material in the mantle or results from a closed-system unmixing of a monosulphide solid solution, sulphides take on a greater importance as possible storers of potassium in the upper mantle and as possible carriers of potassium to the core during the Earth's differentiation.

This raises deep issues on which it would perhaps be unwise to speculate too much until the properties of FSKS have been examined in greater detail. There has recently been considerable debate and disagreement over the role of sulphur, sulphides and potassium carriers in the Earth's lower mantle and core and any new lead in these matters would be welcome. In the meantime, we have at the very least a new natural sulphide, whatever may be its geochemical significance. ☐

Pion production in heavy-ion collisions

from P. E. Hodgson

A RECENT measurement of the frequency of pion emission from the collision of heavy ions has given results that disagree with the predictions of the independent particle model of the nucleus and support the pion condensation model of high-density nuclear states.

The frequency of pion production in free nucleon–nucleon collisions is well known, so if nuclei behave just like groups of independent nucleons it is easy to calculate the expected rate of pion production in collisions between two nuclei at high energies. This model might be expected to be valid at energies high enough for the wavelengths of the interacting nucleons to be rather less than the mean separation of the nucleons in the nucleus. If this is so, the nuclei behave for most purposes as if they are groups of independent nucleons, and the expected rate of pion production is given by the total number of possible nucleon–nucleon interactions, making allowance for multiple scattering and shadowing effects. Significant deviations from the expected number of pions would indicate the presence of strong interactions between the nucleons in the interacting nuclei.

The experimental determination of the pion production rate was made by McNulty *et al.* (*Phys. Rev. Lett.* **38**, 1519, 1977). They exposed a stack of G5 nuclear emulsion to a beam of 280 MeV per nucleon neon nuclei at the Princeton accelerator. Examination of the developed emulsion under the microscope showed the tracks of these neon nuclei, and 189 tracks were found of nuclei that had collided with a nucleus in the emulsion. Many pion tracks were observed originating in these collision events, and careful subsidiary measurements established that pion tracks could be distinguished from those of protons and alpha particles. The results for the rate of pion production as a function of the energy of the neon nuclei, and also for the pion energy spectrum, are shown in the figures.

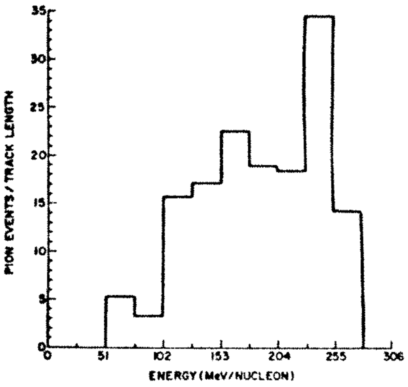

Fig. 1 Pion production as function of neon energy.

A calculation of the rate of pion production expected from the independent particle model has recently been made by Bertsch. He found that the fraction of collisions from which pions emerge should increase from about 1 in 3,000 at the threshold energy of about 54 MeV to about 1 in 27 at energies of 250 MeV per nucleon. This is in complete disagreement with the results shown in the first figure, which show that about 70% of collisions at energies between 100 and 280 MeV per nucleon show pion emission.

Some other calculations of pion production in heavy-ion collisions have been made by Kitazoe *et al.* (*Lett. Nuovo Cim.* **13**, 139; 1975; *Lett. Nuovo Cim.* **14**, 400, 407; 1975) using the

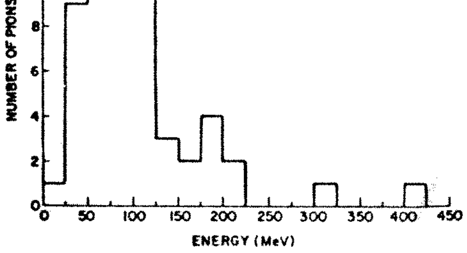

Fig. 2 Pion energy spectrum.

P. E. Hodgson is Lecturer in Nuclear Physics at Oxford University.

hydrodynamic model to include the collective effects on the formation of high-density states in nuclear matter in high energy heavy-ion collisions. In such collisions it is possible for nuclear matter to be compressed momentarily to very high densities, and this could have a considerable effect on the rate of pion production. The high densities are associated with high temperatures, and these can result in pion condensation in just the same way as a gas is ionised with the liberation of electrons when its temperature and pressure are raised. The probability of pion formation can be calculated from statistical theory assuming thermodynamic equilibrium between the pion and nucleon components. In a later paper they reformulated the theory relativistically and evaluated the rate of pion production quantum mechanically.

In particular they calculated the effect of the condensation of zero-momentum pions, and found that this might be appreciable at incident energies of 120 to 440 MeV per nucleon, reaching a peak at an incident energy of about 220 MeV per nucleon. They estimate that as many pions as 0.4 per nucleon may be produced and allowing for those that do not escape from the nucleus gives a result in agreement with the experimental results.

These calculations are still in an early stage, but it is notable that they give results similar to those found experimentally, while those based on the independent particle model are far too low. This indicates that some new process is taking place in energetic collisions between heavy ions, and this should be a strong stimulus to further experimental and theoretical work. ☐

The oddity of blue

from J. D. Mollon

A working party was held in Cambridge in 12-14 July, 1977 to discuss the anomalies presented by the 'blue mechanism' of man's colour vision. The meeting was held at the Kenneth Craik Laboratory, an interdisciplinary laboratory for sensory science, recently founded by the Departments of Physiology and Experimental Psychology, and was supported by a grant from the Cambridge Philosophical Society.

THE first stage of man's colour vision is relatively well understood. It is generally held that there are just three classes of retinal cone, each sensitive to a broad band of the spectrum; and that all our varied experience of hue depends on the comparison, by later neural mechanisms, of the outputs of these receptor cells, each of which is individually colour blind. However, it is increasingly difficult to neglect a catalogue of signs that the blue-sensitive receptor system differs from the green and red-sensitive systems. By special sensory experiments it is possible to study our visual capacities when stimuli are detected only by blue cones and the 'blue mechanism' defined by these experiments turns out to have many odd properties. Moreover, the blue mechanism is disproportionately vulnerable to retinal disease. The working party was held to attempt to sort out these anomalies.

From the discussions emerged three explanatory principles that may account for most of the anomalies of the blue mechanism. Firstly, there are probably rather few blue-sensitive cones. This might explain the poor quantum efficiency and the poor spatial resolution that characterise the blue mechanism as well as the fact that normal observers when matching very small or brief targets resemble the rare class of congenitally colour-blind observers ('tritanopes') who seem to lack blue cones. H. G. Sperling (University of Texas) presented evidence for the relative rarity of blue cones in the baboon retina: measuring the light-induced reduction of nitroblue tetrazolium chloride in the ellipsoids of cones, he found that the putative blue cones (those that stain strongly when exposed to blue light) constitute 12% of the total population of cones over much of the retina and are arranged in a regular mosaic. D. MacLeod, M. Hayhoe and D. Williams (University of California) have demonstrated sharp local variations in the threshold sensitivity of the blue mechanism within an individual human fovea. They also confirmed the finding of Willmer that the very centre of the fovea essentially lacks the blue mechanism. Correspondingly Sperling's measurements suggest that the proportion of blue cones falls to 3–4% at the centre of the fovea.

A second explanatory hypothesis is that signals from blue cones have access only to the 'chromatically opponent' pathways of the visual system, which are thought to carry information about colour. P. Gouras and E. Zrenner (National Institutes of Health, Bethesda) have detected blue-cone inputs in only one class of retinal ganglion cell, which are characterised by tonic responses to blue light and off-responses to long wavelengths. P. Whittle (University of Cambridge) tackled the related and vexed, question of whether the blue cones contribute to brightness as well as to hue: presenting to one eye a flash detectable only by blue clones and to the other a white flash on a white field, he found that some subjects were able to equate the two flashes in brightness while others found the task meaningless.

If indeed signals from blue cones are transmitted only by chromatically opponent pathways, it might be expected that the sensitivity of the psychophysically-defined blue mechanism would be controlled not only by photons absorbed directly in the blue cones but also by signals from long-wavelength cones. E. N. Pugh Jr (University of Pennsylvania) and P. G. Polden and J. D. Mollon (University of Cambridge) suggested that a further group of anomalies could be explained if to the second explanatory hypothesis was added a third assumption: an attenuation of the blue-cone signal occurs at the opponent site and this attenuation depends on the difference of the short and long-wavelength inputs, being minimal when the difference is minimal (and when perhaps our sensation is neither blue nor yellow).

With the two assumptions it seemed possible to explain several phenomena discussed in detail at the meeting: the super-additivity of short and long-wavelength fields in reducing the sensitivity of the blue mechanism (Pugh); a newly-reported and paradoxical increase in the sensitivity of the blue mechanism when yellow light is added to a blue adapting field so as to render the composite field brighter but achromatic (Polden and Mollon); the inflexion that is seen in the threshold-*versus*-intensity function for blue targets on long-wavelength fields (W. S. Stiles); apparent saturation of the blue mechanism (Mollon and Polden); and anomalies of light and dark adaptation (Stiles), such as 'transient tritanopia', the strange loss of sensitivity to blue targets that is found after a long-wavelength adapting field has been turned off and that has now been demonstrated at the ganglion cell level by Gouras and Zrenner and at the level of the b-wave of the electroretinogram by D. van Norren (Institute for Perception, Soesterberg).

Other contributors independently provided results pointing to the second and third hypotheses. Thus R. Boynton (University of California), using pairs of stimuli equated for their effects on both red and green cones and therefore discriminated only by blue cones, has found that such discriminations are impaired by red,

---

J. D. Mollon is a lecturer in Experimental Psychology at the University of Cambridge.

yellow or green fields that have relatively little effect on the blue cones themselves; long-wavelength fields of different wavelength but of the same luminance produce equal losses of discrimination even though their direct effects on the blue cones are very different. M. Alpern and F. Zwas (University of Michigan) have measured the sensitivity of the blue mechanism to adapting beams passing through different points of the pupil and find that the point of entry for best effect is different for short and long wavelength stimuli, suggesting that more than one class of receptor is involved. They add a fresh anomaly to the catalogue: unlike the other cones, the blue cones have their maximal directional and spectral sensitivities at the same wavelength.

Inherited and acquired losses of the blue mechanism may not necessarily result from a loss of blue cones. van Norren demonstrated a blue-cone signal in the electroretinogram of congenital tritanopes; and E. King-Smith, F. Zisman and S. K. Bhargava (University of Manchester) have found that the loss of blue sensitivity in disease is greater for flashes on a yellow field than for flashes on a white field, a result that they relate to the second and third assumptions above.

Lampbrush chromosomes brought up to date

from J. O. Bishop

Nearly 100 years after the discovery of lampbrush chromosomes by Walter Flemming in 1882, what is believed to be the first meeting exclusively devoted to them was held at Maria Laach, in the Eifel in West Germany on May 12–15, 1977. The meeting was arranged by Dr Werner Kunz, University of Düsseldorf, and sponsored by the Deutsche Forschungsgemeinschaft.

DURING the first meiotic division of oogenesis segregation of the chromosomes is suspended, in some organisms for months, after the pairing of homologous bivalents and the formation of chiasmata. The oocyte increases greatly in size and it is reasonable to suppose that, whatever the programme for early embryogenesis, some of its most vital components are laid down at this time. The chromosomes become greatly extended and take up the characteristic lampbrush form in which a chromosome axis, condensed chromomeres and extended lateral loops are all clearly distinguishable in the light microscope.

One feature in particular makes lampbrush chromosomes uniquely interesting. The lateral loops are very actively transcribed. RNA complexed with proteins accumulates on the loops. The form of the RNP complexes and their relationship to the loop vary from one loop to another. This, and the fixed positions of the loops on the axis, makes it possible in some cases to identify the same loop in different oocytes. The RNA products of particular loops can sometimes be identified, and the same loop can be studied at different stages in oogenesis.

Given that a massive increase in the size of the oocyte is necessary, it seems likely that the formation of lampbrush chromosomes is designed to make this possible. The lampbrush form perhaps optimises transcriptional efficiency. On the other hand, since the bivalents are arrested in the process of segregating, perhaps only the parts required for transcription are extended, while the remainder of the chromosome is maintained in a more condensed form. A completely different class of hypotheses is based on the idea that the cell is taking advantage of the growing phase to perform some laborious operation on the chromosomes, such as repair or reconstruction, and that the lampbrush morphology is the result. Of course, these explanations are not mutually exclusive.

It quickly emerged at the meeting that the basis for current thinking about lampbrush chromosomes was laid down between 1950 and 1960, largely due to the work of H. G. Callan in St. Andrews and J. G. Gall at Yale and Minnesota. It was shown that each loop is based on a single extended DNA duplex. When adjacent chromomeres are separated by physical stress, both remain attached to the ends of the intervening loop, suggesting that there is no disruption of the linear continuity of the chromosomal DNA at the junctions of loops and chromomeres. This widely accepted interpretation requires that the pair of chromomeres lying at the base of a loop must be held together by secondary forces. During the 1950s extensive descriptions of lampbrush chromosome sets were published, and genetic polymorphism of loop morphology was discovered. The latter is a strong indication that lampbrush chromosome structure is at least partly determined by the DNA involved.

(from the left) O. Hess, H. G. Callan and E. H. Davidson in discussion.

Transcription

Study of the structure of lampbrush chromosomes is now intimately bound up with inferences as to patterns of transcription. Electron microscope studies of partially deproteinised preparations (O. L. Miller, University of Virginia, Charlottesville) reveal arrays of RNA fibres emanating from a series of polymerase molecules arranged along the loop. In many cases the lengths of the fibres increase regularly along the loop, and this is very reasonably taken to reflect progressive synthesis. Recent autoradiographic studies on *T. c. carnifex* loops that carry histone-specific RNA (see below) are interpreted to show that transcription is initiated before the histone DNA sequences, proceeds through them and continues beyond, with the histone-specifying sequences being cleaved from the transcripts before transcription ends (Callan). Electron microscope studies of loop-associated RNP particles (J. Sommerville, St Andrews) show them to be composed of surprisingly uniform 20-nm particles. The considerably different appearance of the RNP on different loops is apparently due to differences in the quantity and arrangement of these units.

All the evidence available supports the long-standing idea that the lateral loops are transcribed but the chromomeres and the axis are not. Structures with the appearance of transcription complexes are found only on the loops. Antibody to *Drosophila melanogaster* B-form RNA polymerase binds to the loops, but not to the axis or, apparently, to the chromomeres (E. K. F. Bautz; M. Jamrich, Heidelberg).

Provisionally, a transcription unit can be defined as occupying approximately the region between the shortest and the longest fibres observed in an array of transcription complexes (polymerase+fibril). The arrangement of

Caves as islands

from Robert M. May

FOR exploring questions of competition and of island biogeography, the aquatic fauna of caves offers the advantages that the communities are relatively simple (usually fewer than 10 species) and that many replicates exist. Culver (*Am. Nat.* **110**, 945; 1976) has used these facts in an elegant study of the aquatic communities in caves in river valleys in West Virginia, Tennessee and Virginia. Those who saw the movie *Deliverance* will wonder whether the NSF underwrote his insurance.

Although flatworms, molluscs, crayfish and salamanders are occasionally found, the macroscopic fauna in these caves is dominated by isopods and amphipods (two of the many orders of crustaceans), which account for more than 90% of the numbers and biomass in most caves. The streams in most Appalachian caves consist of a series of short riffles separated by larger pools. All the isopod and amphipod species prefer riffles to pools, partly because the rate of flow of food particles per unit of cross-sectional area in the stream is higher. The domain within a riffle is a patchy environment, with the habitable patches underneath rocks separated by uninhabitable areas where the creatures are exposed to the current. Since all the species are generalised detritus feeders, the main competition is simply for places to avoid the current.

Culver (*Ecology* **54**, 102; 1973) has previously shown how, under these circumstances, the coefficients for interspecific competition can be estimated for laboratory studies using artificial streams. The competition coefficients, α, thus obtained are in good agreement with the observed facts about aquatic cave communities: low α-values are associated with species of different sizes (which tend to be under rocks of different sizes); intermediate α-values are associated with species found in different riffles in the same cave; and species never found in the same cave have high α-values. A more detailed analysis of the data available from the laboratory studies shows that communities with three species should be stable and resistant to invasion, which accords with the field observations.

The discussion, based on competition for habitat, explains many of the features of the aquatic cave communities, and suggests most caves could support three species. The average number of species per cave, is, however, more typically two (2.1 species per cave for the Powell River sites, from a total candidate pool of 4 species, and 2.5 species per cave from Greenbriar River sites, from a total pool of 6 species). Culver attributes this to the caves being, in effect, islands. As a consequence, the average number of species per cave is not simply the maximum number consistent with competitive interactions, but rather is some lesser number set by the interplay between extinction and immigration rates.

Such island biogeographical considerations can be worked out in some detail. The upshot of the processes of immigration and local extinction is that any one cave will tend to have fewer species (typically two), and the entire region to have more species (typically four to six), than would be the case if one had the maximum number of stably coexisting species (typically three) in one large cave. This re-echoes a theme first sounded theoretically by Skellam (*Biometrika* **38**, 196; 1951) and Hutchinson (*Am. Nat.* **95**, 137; 1961), with subsequent elaborations by Horn and MacArthur (*Ecology* **53**, 749; 1972) and by Levins and Culver (*Proc. natn. Acad. Sci. U.S.A.* **68**, 1246; 1971). For organisms of this kind, a conservation programme aimed at preserving maximum species diversity would probably be better served by several small refuges rather than one large one (Simberloff & Abele *Science* **191**, 285; 1976). More generally, the optimum pattern for allocation of conservation areas must depend on the life-history details of the target organism.

Culver concludes by emphasising that aquatic cave communities are basically simpler than terrestrial ones. The available evidence indicates, for terrestrial cave communities, that predation rather than competition may play the dominant role, that seasonal changes are more pronounced, and that the available pool of species is greatly affected by local geography. As Culver puts it: 'If you have seen one [type of] cave community, you have not seen them all.'

Robert M. May is the Class of 1877 Professor of Zoology at Princeton University

---

these arrays with respect to the loops varies widely, both within and between species. In many cases a single array occupies all or most of a loop, but some contain a single array which does not span the entire loop, and may occupy as little as 30% (K. E. Scheer, Heidelberg). Other loops contain two arrays, sometimes with the same, and sometimes with opposite polarity. Still others contain multiple arrays—5–10% of the loops in *Triturus*, ~ 50% in the axolotl. When multiple arrays have the same polarity, they may of course represent a single transcription unit with the intervention of one or more processing steps. Where the polarities are opposite this is less likely, and it seems most reasonable to assume for the present that a loop may contain more than one transcription unit.

Organisation

This relates to the relationship between the loops and the axial chromomeres. The proportion of the DNA present in loops is difficult to measure exactly, but it clearly varies widely from one organism to another. In *Triturus* it is put at between 5 and 10%, in *Pleurodeles* and the axolotl at ~50%. At one time it was speculated that each loop is progressively spooled out from one chromomere (the exit strand) and simultaneously gathered up into the other (the re-entrant strand). This is no longer widely believed, and the loops are thought to be more or less constant. The best evidence for this view comes from *Triturus* where it has been shown that the total nuclear RNA corresponds to a transcript of about 5% of the genome—roughly the proportion of the genome found in loops (D. B. Malcolm, St. Andrews). This is not, of course, a rigorous argument.

Techniques have been developed to pick out the same loop or set of loops in different preparations, and in several cases the functions of particular loops have been positively identified. Of the various methods, some depend for their specificity on nucleic acid reassociation, others apparently on the recognition of nucleic acids by proteins, and yet others on antigen–antibody interactions.

Histone genes from a number of echinoderms have been cloned in bacterial plasmids and bacteriophage. Nick-translated cloned DNA has been used to search for the histone genes of *T. c. carnifex* (Callan). Of the five biggish loops in the sexually heteromorphic region of chromosome I, three become labelled with these probes in conditions in which the loop-associated RNA is detected. Four other sets of loops on chromosomes VI(2), X and XI are also labelled. Interestingly, differences were observed between the loop-sets of heterozygous bivalents in two cases, and minor differences between different newts are seen. A loop that is not otherwise visible, presumably because it carries little matrix, is visualised autoradiographically by this technique. What seem to be the same loops can also be labelled (along with others) by using nick-translated middle-repetitive *T. c. carnifex* nuclear DNA, isolated by conventional reassociation methods (H. C. Macgregor, Leicester). The same middle-repetitive fraction of *Triturus* DNA labels six loops near the centromeres of *Plethodon* lampbrush chromosomes perhaps indicating the evolutionary conservation of some families of sequences. A more remarkable conservation is suggested by the labelling of loops in chromosomes II and XI of *Triturus* by human and lungfish DNA (Gall).

Labelled 5S RNA or DNA of *Notophthalmus viridescens* labels loops near the centromeres of chromosomes I, II, VI and VII (P. J. Pukkila, NIMR, London). That of *Triturus c. carnifex* labels a loop on chromosome X. The 5S RNA of the developing oocyte accumulates, together with 4S RNA, in a 40S cytoplasmic RNP particle which predominantly contains only two proteins with molecular weights of 38,000 and 49,000. Antibodies against one of these bind to a loop pair on chromosome X which may be identical to the 5S sequence loop (Sommerville). Antibody against the other binds to several pairs of loops. Antibody raised against a 32,000 dalton protein isolated from the very complex nuclear RNP binds preferentially to 12 pairs of loops. In yet another approach, nick-translated single-stranded DNA binds to two dozen specific loops in conditions that do not favour nucleic acid reassociation, and does so only if RNA has been removed from the preparation (Gall).

Messengers and maturation

Reassociation experiments indicate that the RNA of the oocyte cytoplasm contains only part of the coding potential of the organism. In *Xenopus* the poly(A) RNA of the tadpole contains sequences not found in the oocyte (J. O. Bishop, University of Edinburgh). Similarly, the *Strongylocentrotus* blastula contains mRNA sequences not found in the oocyte (E. H. Davidson, CalTech). On the other hand evidence was presented suggesting that mRNA sequences for both adult and tadpole globin are present at low concentration in *Xenopus* oocytes (M. Rosbash, Brandeis University). It is not really difficult to resolve these results, but we are left without a firm conclusion. On the one side, the reassociation experiments may have failed to detect sequences present in very few copies. On the other, it is possible that sequences with the potential for a very high level of expression also have a relatively high 'leakage' rate when repressed.

Whichever way this question is resolved, it has little direct bearing on the significance of lampbrush loop transcription. Should the oocyte mRNA not contain sequences found elsewhere, those sequences might still be transcribed in the germinal vesicle. A few copies of all mRNAs might reflect a low level of escape synthesis under repression, or synthesis at the derepressed level in an occasional oocyte, rather than synthesis of particular significance.

It is perhaps more profitable to ask to what extent the transcriptional activity of the loops is necessary to account for the RNA present at maturity. Here *Xenopus* and *Strongylocentrotus* are markedly different. A comparison of the poly(A) RNA of stage II (previtellogenic), III and VI (mature) *Xenopus* oocytes by reassociation methods shows them to be qualitatively identical (P. J. Ford, University of Edinburgh). The difference in abundance between the more and less abundant sequences narrows during maturation. Direct measurements indicate that the mRNA synthesised in young oocytes is completely stable. It seems that mRNA is steadily accumulating during maturation, and the synthesis of the more abundant sequences (possibly transcribed from repetitive genes such as histones) is perhaps slowing down. In amphibian oocytes, histone mRNA is largely polyadenylated (M. L. Pardue, Massachusetts Institute of Technology). Calculations based on estimates of the number of active RNA polymerase molecules and the size of the precursor agree that about 3 months would be required to synthesise the number of copies of each sequence found in the mature oocyte (10^6 per oocyte of the less abundant). In *Strongylocentrotus* on the other hand the much smaller complement of RNA can be synthesised in a day, and yet maturation in this organism also takes months (Davidson). A repeated turnover of RNA in the maturing oocyte must therefore occur, which is reflected in the blastula and gastrula: at each stage the bulk of the RNA present is newly transcribed. This applies not only to newly appearing sequences, but also to those common to the previous stage. In *Strongylocentrotus*, therefore, it seems that the accumulation of a store of nascent mRNA for utilisation in early embroyogenesis is not a primary function of the period of oogenesis.

This is not to say that nascent mRNA has no part to play. In both amphibians and echinoderms mRNA is mobilised around the time of fertilisation. It is easy to believe that it plays a part at least in the early cleavage stages. About one third of the oocyte sequences are not found in *Xenopus* tadpoles (Bishop) and in *Strongylocentrotus* two thirds of the sequences found in the oocyte are not found in the pluteus (Hough-Evans).

A hundred years ago

THE next eclipse of the moon is attracting the notice of physicists and aëronauts in France. It is proposed to make a balloon ascent during the night of August 23–24, in order to ascertain whether, independently of clouds, the eclipsed moon has a bloody tinge.

From *Nature* **16**, 16 August, 335; 1877.

Spermatocytes

Spermatocytes also show lampbrush chromosomes. In primary spermatocytes of *Chironomus*, lampbrush chromosomes with thousands of loops are clearly visible in the electron microscope but no transcription complexes are seen (H. G. Keyl, Bochum). In spermatocytes of *Drosophila hydei*, however, the Y chromosome forms at least five pairs of morphogenetically distinctive loop structures that closely resemble oocyte lampbrush loops. Apart from the bobbed loci, Y chromosomes in *Drosophila* carry no classical morphological markers. They do, however, carry genetically defined fertility factors, and these have been closely studied in *D. hydei* (O. Hess, University of Düsseldorf). A genetic deficiency of one or another loop is always accompanied by failure of fertility. Some years ago, Hennig (*J. molec. Biol.* **38**, 227; 1968) showed that the spermatocytes contain Y chromosome-specific RNA. Also, treatment with actinomycin D causes regression of the loops. In spread preparations transcription complexes are observed (K. H. Glätzer, Düsseldorf). One pair of loops, however, called threads, shows some peculiarities. The pattern of uridine incorporation, the binding sites of RNA polymerase antibodies, and the matrix morphology suggest that the distal parts of the threads are not active in transcription but seem to function as RNP storage organelles. But other explanations are clearly possible.

The relationship of the spermatocyte lampbrush Y chromosome to oocyte lampbrushes is not all clear. However, this system is most promising in its own right, both because of the localised effect of the fertility factors and because a truly cytogenetic approach is clearly possible. ☐

review article

Taxonomy and the origin and evolution of cultivated plants in the New World

Barbara Pickersgill*

Current taxonomic problems in cultivated plants include delimitation of species, whether speciation has occurred under domestication, and the role of weedy relatives in the evolution of domesticates. Many cultivated plants of the New World seem to have been domesticated not once but several times, and agriculture itself may well have originated independently in four different parts of the Americas.

STUDIES of the origin and evolution of cultivated plants aim to answer four basic questions: from what did our modern crop plants originate; where were they domesticated; when did this happen; and how have these crops changed and spread since they were first taken into cultivation? In 1886, Alphonse de Candolle[1] outlined the pertinent sources of data in order of usefulness: first, archaeology; second, botany; third, history; fourth, philology. Today all these types of evidence are still used, though 'botany' in de Candolle's sense has become the province of taxonomy in particular, and involves more than gross morphology and geographical distribution. Cytotaxonomic studies are now routine, while chemotaxonomy may furnish additional information on relationships. New micromorphological characters have become available with the development of the scanning electron microscope and, together with improved archaeological techniques for the recovery of plant material, are greatly assisting identification and analysis of archaeobotanical specimens. Numerical taxonomic techniques enable taxonomists to analyse variability and assess resemblances using many variables, from many different fields, simultaneously.

Species concepts in cultivated plants

When investigating the origin(s) of a particular crop, the first essential is to know how many species are included in that crop. Although Darwin[2] and de Candolle[1] called attention to the striking and discontinuous intraspecific variation characteristic of cultivated plants, taxonomists of the period often elevated these variants to the rank of species. With the rediscovery of Mendelian genetics, many of these 'species' were correctly evaluated as simply lines differing in one or a few major genes. The development of genecology focussed attention on the process of speciation, particularly the role of reproductive isolation in the differentiation of species. This likewise led to the recognition of fewer, but more variable, species. The taxonomist's task is to distinguish between discontinuities which may seem very striking but which nevertheless represent simply major gene variants within a cultivated species, and discontinuities which may appear trivial but which delimit boundaries between species.

The effect of these changing species concepts is well illustrated by the chili peppers (*Capsicum*). In the nineteenth century, over 60 species were described, differing mostly in colour, size, shape and pungency of the fruit. In 1923, Bailey[3] reduced these to a single species. Now, five different species of domesticated chili pepper are recognised[4], mainly by floral characters, since the more strikingly discontinuous fruit characters show parallel variation within the domesticated species.

Speciation and domestication

Improved taxonomic understanding of other crops has shown that not only *Capsicum*, but also cotton, tobacco, beans, squash and amaranth, among others, comprise two or more cultivated species, grown for the same product and used in the same way, but usually with their own characteristic geographical distributions[5]. This poses the problem of whether speciation preceded domestication (which implies that the individual cultivated species were domesticated independently, from wild ancestors which were already specifically distinct), or whether speciation followed domestication (in which case each crop may have been domesticated once only). This question has to be answered separately for each crop, and the answers may well be different.

In cotton, truly wild plants (not escapes) are known in both Mesoamerican *Gossypium hirsutum* and South American *G. barbadense*. The earliest archaeological cotton from South America belongs to *G. barbadense* and seems to represent a very early stage in domestication[6]. The earliest Mexican archaeological cotton is, however, 'almost certainly' *G. hirsutum* and is fully domesticated, although it is older than the earliest Peruvian specimens[7]. These data strongly suggest independent domestication of the two cultivated species of New World cotton from specifically distinct wild ancestors.

Among South American cultivated diploid potatoes, on the other hand, four species have been recognised[8]. *Solanum stenotomum* is the basic, and most variable, species. *Solanum goniocalyx* is a northern derivative which consists of a few relatively invariable clones. *Solanum ajanhuiri* probably results from hybridisation between cultivated *S. stenotomum* and the wild frost-resistant species, *S. megistacrolobum*[9]. *Solanum phureja*, adapted to the wet eastern slopes of the Andes and distinguished by early maturity and non-dormant tubers, was perhaps derived by assortative mating within the original variable cultivated complex[10]. Here, domestication has been followed by increasing differentiation, to the verge of speciation, within the cultivated populations.

Chili peppers present a more complex situation. Of the five domesticated species, *Capsicum baccatum* and *C. pubescens* are morphologically and cytogenetically so distinct that they must each have been domesticated independently from distinct wild species.

Numerical taxonomic studies[11] confirm the probable independent domestication of *C. baccatum* but suggest that domesticated *C. annuum*, *C. chinense* and *C. frutescens* all arose from different parts of the same incompletely differentiated complex of wild forms. In chili peppers, therefore, speciation in some instances preceded, and in other instances was accentuated by, domestication.

The role of weedy relatives

Often the closest wild relatives of a cultivated plant prove to be weedy forms in the same, or a closely related, species. As de Candolle[1] noted, distinguishing genuinely wild ancestors from feral descendants of a crop is often very difficult. Again, the problem must be evaluated independently for each crop and the decisive evidence may come from very different sources.

In cotton[12], primitively wild forms have small bolls, often with sharp recurved beaks, and greyish-white or dingy brown lint sparsely covering the small hard seeds, which are dispersed individually. The beak has been reduced in size in hand-harvested domesticated cottons and has not been regained in feral cottons. Feral cottons also retain the clear white or uniformly brown lint of their cultivated ancestors and their lint is usually so abundant that all seeds in one locule of the boll are dispersed as a unit. Critical analysis of morphological features may thus permit primitively wild cottons to be distinguished from escaped feral forms.

In *Cucurbita*[13], there has been argument over whether weedy *C. andreana* is the wild ancestor or an escaped derivative of the South American cultivated *C. maxima*. With the exception of *C. ecuadorensis*, whose status also seems doubtful, no other wild species of *Cucurbita* is known from South America. *Cucurbita* flowers are pollinated by various insects, including squash bees *(Peponapis)* which are wholly dependent, as larvae and adults, on *Cucurbita* flowers for food. Three species, representing three different subgenera of *Peponapis*, are confined to South America. It seems unlikely that South American *Peponapis* could have diverged as much as this if *Cucurbita* had been introduced by man (hence comparatively recently) from Middle to South America. Here, then, taxonomic study of the pollinator suggests an ancient presence of more than one species of *Cucurbita* in South America, presumably including *C. andreana*, hitherto considered only doubtfully wild.

Many wild chili peppers also occur in weedy contexts, raising doubts about their relationships to the domesticates. Virtually all accessions of domesticated *Capsicum annuum* belong to the same, derived, chromosome race, which in wild *C. annuum* occurs only in Mexico[14]. Other wild forms of *C. annuum* carry the basic karyotype shared by most species in the genus. Cytological data thus strongly suggest that weedy forms of *C. annuum* are primitively wild and that only the Mexican weedy forms are involved in the origin of domesticated *C. annuum*.

Electrophoretic studies on isozyme variability may also help in unravelling relationships between cultivated and weedy races. The New World cultivated chenopods include one tetraploid, *Chenopodium nuttalliae*, in Mexico and one tetraploid, *C. quinoa*, in the Andes. The two are very similar and there has been some doubt as to whether they really represent distinct species. Weedy tetraploids also occur in the Andes *(C. hircinum)* and from Mexico north into North America *(C. berlandieri)*. All the tetraploids carry two unlinked genes for synthesis of the enzyme leucine aminopeptidase (LAP) (ref. 15). Virtually all Andean accessions of cultivated *C. quinoa* and weedy *C. hircinum* are homozygous for *Lap-A2* and *Lap-B2*. Mexican cultivated *C. nuttalliae* and weedy *C. berlandieri* are also homozygous for *Lap-A2* but at the *Lap-B* locus they carry *Lap-B1* not *Lap-B2*. In North America, outside the range of *C. nuttalliae*, *C. berlandieri* is polymorphic for *Lap-A* and monomorphic for *Lap-B2*. These studies support the view that *C. nuttalliae* and *C. quinoa* are distinct species; fit with earlier data on genetic control of fruit colour which imply that pale-fruited domesticated forms of *C. nuttalliae* and *C. quinoa* originated independently[16]; and suggest that weedy *C. berlandieri*, at least, is more likely to be ancestral to its related cultigen than derived from it.

Origins of polyploid crops

Many New World cultivated plants are polyploids and here the direction of evolution, from diploid to polyploid, is unequivocal. The initial steps in determining the ancestry of a polyploid are now largely routine, but the results of these investigations are interpreted more cautiously than was the case a decade or so ago. The potato has many attributes of an autotetraploid, with four homologous sets of chromosomes, but forms mainly bivalents at meiosis[17], that is, shows pairing behaviour usually associated with allopolyploidy. Cotton is a classic allotetraploid, but in AD polyhaploids derived from the AADD cultivated cottons there is less pairing between A and D chromosomes than occurs in newly synthesised AD hybrids[18]. This suggests a genetic restriction of pairing between A and D chromosomes which exaggerates the apparent difference between the two genomes. Chromosome pairing alone may thus be an unreliable guide to the nature and origin of a polyploid.

Comparative morphology may also be misleading. The most probable ancestor of the cultivated tetraploid potato (*Solanum tuberosum*) is the cultivated diploid *S. stenotomum*. *Solanum stenotomum* has, however, an irregular bilabiate calyx, while the calyx of *S. tuberosum* is always regular. The irregular calyx of *S. stenotomum* is recessive to the regular calyx of the weedy diploid *S. sparsipilum*, and Hawkes[8] has postulated that tetraploid *S. tuberosum* arose by chromosome doubling in a hybrid between *S. stenotomum* and *S. sparsipilum*. Apparent confirmation of this parentage has come from serological and electrophoretic studies[19], as well as observations on polyhaploids of *S. tuberosum*[20], some of which have an irregular, others a regular, calyx.

Different lines of investigation sometimes suggest different conclusions. *Nicotiana tabacum* is an allotetraploid combining the S genome from *N. sylvestris* and the T genome from one of the four species in section Tomentosae. Geographic distribution and fertility of synthesised amphidiploids suggest the T genome donor was *N. otophora*, while morphology of the synthesised amphidiploids, genetic segregation ratios in hexaploid hybrids between *N. tabacum* and the T genome diploids, and chemotaxonomic studies on sterol composition and isozyme variation all implicate *N. tomentosiformis* rather than *N. otophora*[21,22]. A possible explanation of these discrepancies is that the T genome of *N. tabacum* was not derived from any of the extant species but from an extinct progenitor common to both *N. tomentosiformis* and *N. otophora*, though this raises a further problem since *N. tabacum* is unknown in the wild and is usually assumed to have originated in cultivation, that is, fairly recently on the evolutionary time scale.

The question of multiple origins arises again in polyploid crops. If their ancestral diploids were widespread, hybridisation, chromosome doubling and successful establishment of the resultant polyploids could have occurred more than once and in more than one place. For example, a polyphyletic origin has been postulated, on chemotaxonomic grounds, for the tetraploid New World cottons. Johnson[23] argued, from seed protein electrophoretic patterns, that *Gossypium hirsutum* arose from hybridisation between an AA diploid and two different DD diploids, while studies of floral pigments[24] may imply that different DD diploids were involved in the origins of *G. hirsutum* and *G. barbadense* respectively. These two interpretations are in part mutually contradictory, and do not agree with cytogenetic evidence that the D genomes of *G. hirsutum* and *G. barbadense* are identical[25]. Nevertheless, polyphyletic origins must be borne in mind when polyploid crops are considered.

Taxonomy and the domestication and dispersal of cultivated plants

Although the archaeological record potentially provides the most conclusive evidence on where a particular crop was domesticated, this record is so incomplete that inferences often have to be drawn instead from the present distribution of the crop and its wild relatives. Criteria usually used to determine the species most closely related to a crop are morphological similarity and ability to hybridise with the crop. However, in some groups, such as *Manihot*, speciation has not been accompanied by reproductive isolation so this latter criterion is useless. Rogers and Appan[26] resorted to numerical taxonomic analyses in an attempt to determine where and from which species cultivated manioc (*M. esculenta*) was derived. They found that species morphologically close to *M. esculenta* occur in both Middle and South America, so were unable to decide in which continent *M. esculenta* arose.

Improved taxonomic understanding may radically alter views on the wild relatives and hence place of origin of particular cultivated plants. The coconut (*Cocos nucifera*)[27] was once thought to have originated in the New World because this was where the other species of *Cocos* occurred. Now, however, *Cocos* is treated as a monotypic genus whose closest living relative is African. This, together with the fossil record of the coconut and its variability and range of uses in south-east Asia, suggests that the coconut originated in the western Pacific and spread west to east, not east to west, across the ocean. The bottle gourd (*Lagenaria siceraria*) is another pantropical cultivated plant unknown in the wild and considered for a long time to be the only species in its genus. Now, however, two African genera have been merged with *Lagenaria*[28], in part because they readily give fertile hybrids with the bottle gourd, and it now seems that *L. siceraria* itself may have originated in Africa.

Both coconut and bottle gourd have figured largely in arguments about prehistoric human trans-oceanic voyages. Archaeologists and geographers tend to be struck by the coincidence of similar uses of similar plants on different sides of an ocean; botanists, aware that these same disjunct distributions are shared by various wild plants which are no conceivable use to man, are not found in man-disturbed habitats, and are hence most unlikely to have been spread either accidentally or intentionally by man, are usually less impressed. Seventy-four genera, including 108 species, are common to tropical America and tropical West Africa; 94 genera occur in both tropical South America and tropical Asia–Australasia[29]. Many of the species involved are far less well-adapted for natural long-distance dispersal than the coconut or the bottle gourd.

Centres of diversity and centres of domestication

Vavilov[30] employed the argument that centre of diversity is a guide to centre of domestication extensively in his studies on the origin of cultivated plants, though he was careful to distinguish primary centres, where diversity is a consequence of ancient cultivation, from secondary centres, where diversity may be a consequence of hybridisation. Later critics of Vavilov's work have suggested that ecological diversity[31], farming practice[32], human migration patterns[33] and/or the breeding system of the crop[34] could likewise produce localised centres of diversity, in which diversity would however be unrelated to the length of time for which the crop had been cultivated. Some cultivated plants, such as the bottle gourd, may have no centre of diversity, but were probably domesticated repeatedly throughout the range of their wild progenitors[35]. Despite the availability of appropriate techniques—notably isozyme analysis—for comparative studies of variation, and despite the interest among those concerned with conservation of crop genetic resources in knowing more about distribution of variability within crops as a guide to exploration and sampling, there have been few thorough biosystematic investigations of cultivated plants inside and outside the range of their wild relatives[36,37] and it remains difficult to determine how generally applicable Vavilov's criteria are for determining the place of domestication of a cultivated plant.

Maize is a classic example of a crop in which variability may give misleading evidence on place of domestication. The centre of diversity of maize is in Peru, yet archaeological evidence and distribution of wild relatives demonstrate conclusively that maize was domesticated in Mexico[38]. In tomato also the centre of diversity of the cultigen (Mexico) and the distribution of related wild species (western South America) do not coincide. Here archaeological, historical and linguistic data indicate that Mexico was the centre of domestication[39].

Taxonomy and the archaeological record

Interpretation of the archaeological record of cultivated plants is very much the province of taxonomy. The first step is identification and, because seeds and other hard plant parts are more likely to be preserved than fleshy fruits, flowers or unlignified vegetative organs, identification usually cannot be based on traditional taxonomic diagnostic characters but has to rely instead on such characters as are available. Scanning electron microscope studies of surface features of carrot mericarps from late, possibly post-Spanish, levels of a site in coastal Peru showed that these fruits belonged to one of the indigenous New World wild species, not the introduced Mediterranean *Daucus carota* (B.P., unpublished, and S. Okeke, personal communication). Similarly, scanning electron microscope studies of starch grains and vascular tissue, particularly xylem, seem to offer the best hope of identifying various starchy tubers and roots from other Peruvian sites[40]. Phytoliths (siliceous bodies in the epidermal cells of many grasses, whose shape may differ in different genera) may be preserved archaeologically when most other plant parts have decayed and attempts are being made to use phytoliths to trace the spread of maize cultivation from Mexico to South America (D. M. Pearsall, papers delivered at the 41st and 42nd Annual Meetings of the Society for American Archaeology, 1976 and 1977), through humid tropical regions where archaeobotanical preservation is generally poor.

After identification, the next step is to decide whether the archaeobotanical material comes from wild or domesticated plants. Sometimes domestication has been accompanied by morphological changes that can be recognised in archaeological specimens. In *Phaseolus vulgaris*[41], both the parchment layer and the fibrous thickening of the sutures of the pods have been reduced, producing tardily dehiscent or indehiscent pods in the cultigens. The structure of the seed coat has also altered so that seeds of domesticated beans are more permeable, hence germinate more rapidly. In chili peppers[42], natural mechanisms for seed dispersal have likewise been lost, and fruits of domesticated peppers are retained on the peduncle at maturity.

In many crops domestication has not been accompanied by qualitative changes of a sort that could be detected archaeologically. Quantitative changes in size have been extensively used in studies of animal domestication but are treated more cautiously by botanists. Exploitation, cultivation and domestication of avocadoes have been distinguished at different periods of a long archaeological sequence from Mexico[43], but this interpretation has been criticised because both parameters used (numbers of seeds, and size of largest seed) are themselves in part related to time[44]. Archaeological fruits of sunflower, *Chenopodium* and *Iva* from sites in eastern North America which antedate the spread of maize agriculture from Mexico are larger than fruits of modern weedy forms. Those who do not believe that agriculture was invented independently by the Eastern Indians have argued that growth on nutrient-rich soils such as middens, selective harvesting and/or post-harvest processing could lead to fruits recovered from archaeological contexts being outside the size range of modern wild fruits; proponents of the hypothesis have pointed out that other weedy plants, such as *Phalaris*, which were collected but not cultivated, do not have larger fruits than modern forms[45]. *Iva* has in addition been found archaeologically east of its present range as a wild plant, suggesting that man was involved in the spread of this species[46].

Agricultural origins in the Americas

De Candolle[1] considered that agriculture had originated independently in three regions: China; the Middle East and Egypt; and tropical America. Vavilov[30] recognised eight centres of origin of cultivated plants, including two in the New World. More recent taxonomic studies of New World cultivated plants and collaboration between taxonomists and archaeologists in interpreting evidence on their domestication, evolution and spread suggest that agriculture may have developed essentially independently in four different parts of the Americas. In Mesoamerica and the Andes the first unequivocal domesticates appear about the same time, 5500–5000 BC (ref. 46), but the plants cultivated in these two centres appear in a different sequence and often belong to different species. Later some crops, notably maize, were exchanged between the two areas, but the introduced crops were absorbed into the indigenous agricultural complexes without altering the essentially distinctive character of the two regions. A third complex of crops was domesticated in the humid lowland tropics, but it is difficult to determine how early agriculture began here because conditions seldom favour preservation of identifiable archaeobotanical materials. Lowland domesticates which could survive in semi-arid conditions (manioc, sweet potato, peanut, pineapple) spread to the Mesoamerican and Andean centres, while crops which could adapt to high rainfall (maize, cotton) spread down into the jungle lowlands. In eastern North America a fourth complex of cultivated plants may have developed, but this was almost completely supplanted by the northwards spread of the Mesoamerican domesticates.

Multiple origins thus seem likely for New World agriculture in general as well as for most of those New World crops which include more than one species. Further and more critical taxonomic and archaeological work may well demonstrate that even single-species crops may have been domesticated repeatedly within the range of their wild progenitors. Domestication of cultivated plants no longer seems to be as unique and difficult a process as was once thought.

Oceanic residence times of trace metals

J. M. Bewers & P. A. Yeats
Bedford Institute of Oceanography, Dartmouth, Nova Scotia, Canada

A detailed study of suspended matter and metal fluxes in a large marginal sea has enabled us to assess the impact of nearshore precipitation of the dissolved and particulate constituents of river discharge upon the oceanic residence times of seven trace metals. A distinct improvement in the agreement between stream flow and sedimentation rate estimates of residence time has been achieved and we conclude that most previous determinations, particularly in the cases of Fe and Mn, have been overestimated. Our calculations yield oceanic residence times of Fe which are compatible with direct measurements of the settling rate of Fe in the deep ocean.

THE oceanic residence times of trace metals have most commonly been estimated by determining either the rates of metal injection to the ocean from rivers (the stream-flow method) or the rates of metal precipitation into oceanic sediments. In a majority of cases, the metal concentrations used in these calculations to determine the standing stock of metals in the ocean have not been the most recent and reliable estimates. This has generally led to overestimates of residence time irrespective of which method has been used. In addition, estimates based on stream-flow have largely neglected both nearshore precipitation of metals and the discharge of metals to the ocean in riverborne suspended particulate material. Obviously, for metals that are predominantly in solution in rivers, and which do not undergo appreciable precipitation in estuaries, neither of these considerations will seriously alter the calculated residence times. For elements such as Fe, however, which significantly precipitate in estuaries[1–4], residence times calculated without accounting for this removal will be underestimated. Conversely, although most riverborne particulates undoubtedly precipitate in the nearshore zone, the residual particulate flux will contribute large amounts of some metals, for example, Fe and Mn to the ocean. If these fluxes are neglected, stream flow residence times will be overestimated.

It may be argued that such biases would be revealed by a comparison of the rate of incorporation in sediments with the rate

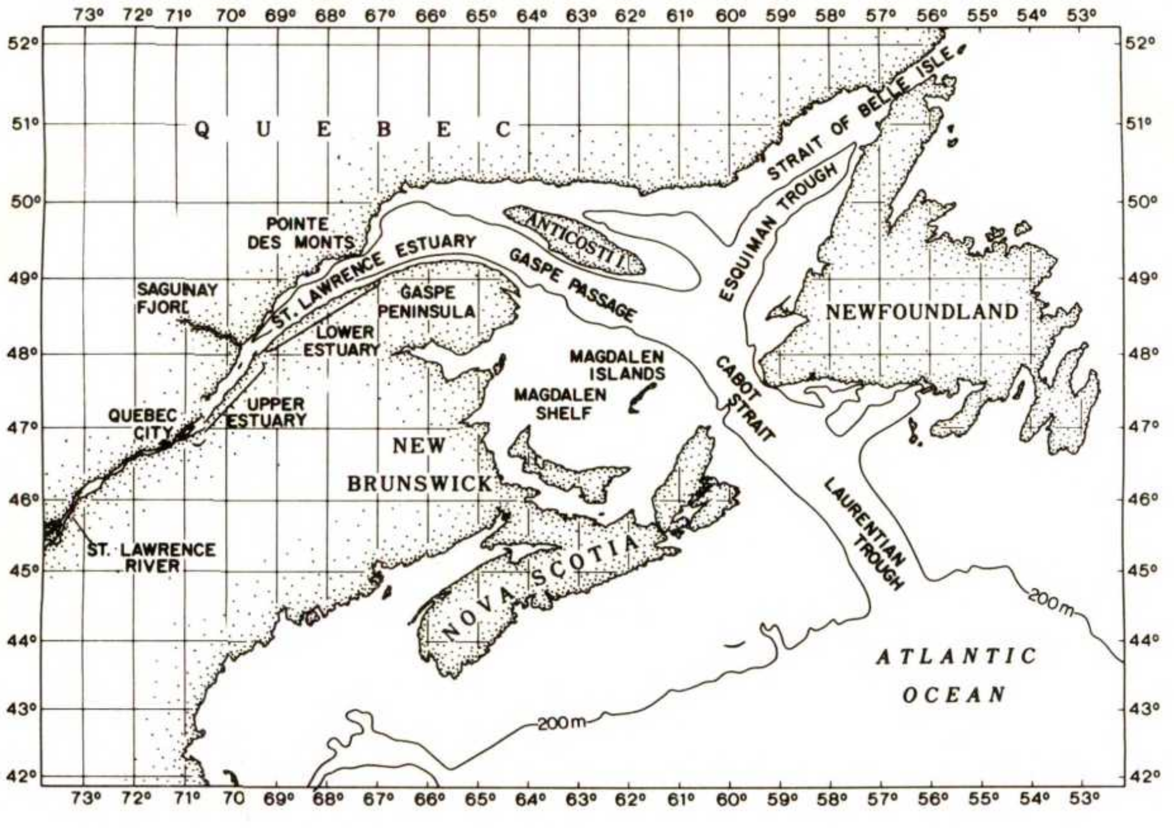

Fig. 1 Estuary and Gulf of St Lawrence.

of injection from rivers. We seek to show that this is indeed the case, and that taking into account (1) the extent of nearshore metal precipitation and (2) the particulate as well as the dissolved, river discharges of each metal, results in improved agreement between stream flow and sedimentation rate estimates of oceanic residence times. The use of recent values for oceanic trace metal concentrations should also improve the accuracy of these estimates.

This paper is based on data collected on chemical oceanographic surveys of the St Lawrence river, estuary and Gulf of St Lawrence, the Saguenay Fjord, and the western North Atlantic during the period 1972–1976. The estuary and Gulf of St Lawrence (Fig. 1) comprise a large marginal sea on the eastern seaboard of North America. Of the freshwater input to the entire system, 71% is derived from the St Lawrence River which is the eleventh largest world river in terms of water discharge. We have determined the concentrations of suspended particulate matter (SPM) and seven metals in inflowing fresh and saline waters and outflowing mixed water at the two extremities of the system (Quebec City and Cabot Strait) and at two other sections in the estuarine region (near the entrance to the Saguenay Fjord and at Pointe des Monts). Nuclepore filters (0.4 μm pore size) were used for the gravimetric determination of SPM concentrations and the metals were analysed in unfiltered samples (Fe, Mn, Co, Ni, Cu, Zn, Cd) and filtered samples (Fe, Mn) by flameless atomic absorption techniques. The resultant data have been used in a mass and salt conservation model (Fig. 2) to calculate the fluxes of each metal flowing into and out of three sequential regions of the entire marginal sea (Table 1). Since these data probably only pertain to the instantaneous fluxes at the time of sample collection, it would be unrealistic to use them for estimating the integrated annual fluxes at each section. We have only assumed, therefore, that the proportions of each component precipitated, or otherwise removed, within each region of the system remain unaltered as stream flows change with season. It has also been assumed that direct atmospheric precipitation of particulates and trace metals into the system is negligible and that exchanges through the Strait of Belle Isle, which, for water, are about 1% of those at Cabot Strait, can be ignored. In the former respect, particulate atmospheric deposition has been estimated to be about 1% of the overall freshwater particulate input[6]. Finally, since the St Lawrence River is unlikely to be the sole source of sediments within the system, we have assumed that, for each metal, the percentage losses from all freshwater and marine sources are identical. As an independent assessment of the validity of the calculation we also compare in Table 1 the concentration of each metal in the internally precipitating material with the composition of pelitic sediments within the Gulf. The comparison is surprisingly good. Similarly, the calculated sedimentation rate of 415 kg s^{-1} (1.3 × 10^{7} t yr^{-1}) agrees well with Sundby's[6] estimate (1.0 × 10^{7} t yr^{-1}) of the rate at which fine-grained sediments have accumulated during the present circulation regime.

The results of scaling the St Lawrence data to the global situation are illustrated in Table 2. We first determined the weighted average composition of St Lawrence River water based

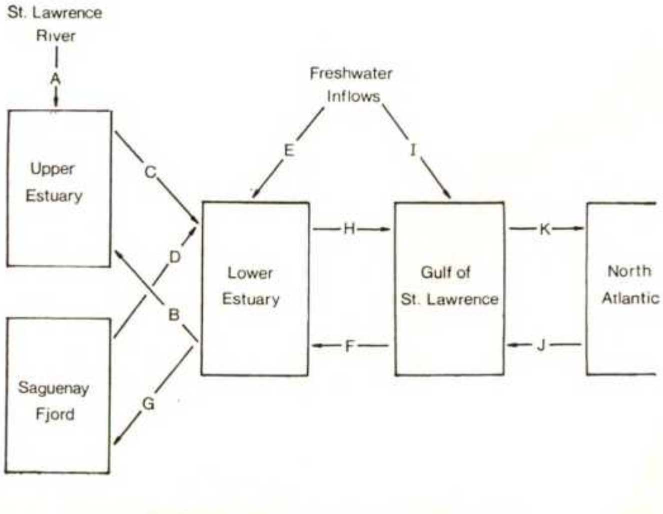

Fig. 2 Model of the St Lawrence system.

Table 1 Fluxes of suspended matter and metals through the St Lawrence system

Subscripts d, p and t denote dissolved, particulate and total metal respectively.
Characterisation of water flows in Cabot Strait and Pte. des Monts sections are based upon the geostrophic calculations of El-Sabh[20].

on duplicate samples collected at two stations on a section across the river at Quebec City for the months April to September inclusive. We then calculated the resulting river-derived annual fluxes through Cabot Strait by correcting for the deposition of the river constituents within the entire marginal sea. Estimates of the particulate fraction of each metal in the Cabot Strait outflow were then used to split the total fluxes into dissolved and particulate components. For Fe and Mn, these estimates are based upon experimental determinations while others are calculated from average terrigenous rock composition and the concentrations of total metal and suspended matter in the outflow. The dissolved and particulate metal fluxes have then been scaled up to the world river discharge on the assumption that the losses of river-derived material in the Gulf of St Lawrence are typical of those in the nearshore receiving waters of all world rivers. The scaling has been achieved by using Holeman's[7] figure for the particulate material discharge via rivers to scale the fluxes of particulate metal and Livingstone's[8] value for the world river water runoff to scale the fluxes of dissolved metal. Implicit in the former scaling process is the assumption that the composition of particulate material discharged by other rivers is similar to that found in the case of the St Lawrence. Since the composition of weathered terrigenous rock is not greatly variant, especially in the cases of Fe and Mn, this assumption is not unreasonable. Similarly implicit in the dissolved metal scaling process is the assumption that the dissolved composition of St Lawrence River water is typical of that of world rivers. Obviously, the validity of this assumption must await more accurate estimates of the composition of other major river waters but the values we have used are well within the range of commonly accepted values for other fresh water discharges.

Having carried out this scaling process it is a simple matter to recombine the dissolved and particulate metal fractions and calculate the oceanic residence times using 1.32×10^{21} *l* as the volume of water within the oceanic basins and the average concentration of each metal in oceanic waters shown in Table 2, after Bewers *et al.*[9]. Comparisons between these latter concentrations and other previously reported values are made in this reference. The agreement with values reported more recently[10–12] is good. The results of such a calculation and a comparison with residence time estimates based on those of Goldberg and Arrenhius[13] but using the recent oceanic metal concentrations are also shown in Table 2.

We have not attempted to calculate the residence time of particulate material since this requires a better knowledge of the mean concentration of purely detrital material in the deep ocean. Nevertheless, we have included in Table 2 an estimate of the suspended particulate influx to the ocean although we realise that its acceptance implies that there is no substantial export of internally generated biogenic particles through Cabot Strait. If the terrigenous detrital component of particulate material is diluted with internally generated biogenic particles the nearshore losses of suspended matter will be underestimated. Our estimates of particulate fluxes at Cabot Strait are, however, based on measurements in July 1976 at which time the composition and quantity of suspended matter in the Gulf of St Lawrence outflow indicate that the material is predominantly detrital.

Table 2 Residence time calculations

	Units	SPM	Fe	Mn	Co	Ni	Cu	Zn	Cd
Annual outflow from St Lawrence River	kg yr^{-1}	4.4×10^{9}	3.8×10^{8}	1.0×10^{7}	1.4×10^{5}	7.6×10^{5}	1.4×10^{6}	2.2×10^{6}	1.2×10^{5}
River flux corrected for nearshore losses	kg yr^{-1}	3.08×10^{8}	4.18×10^{7}	5.30×10^{6}	1.05×10^{5}	6.69×10^{5}	1.25×10^{6}	2.20×10^{6}	1.02×10^{5}

Oceanic residence time based on sedimentation rate	yr	—	30	53	780	1800	6400	18000	92000

*Assumed mean Cd concentration in ocean sediments of 0.42 mg kg^{-1} (ref. 21)
Global dissolved flux based on scaling river water discharge to world river runoff of 3.24×10^{16} kg yr^{-1} (ref. 8)
Global particulate flux based on scaling river particulate discharge to world river sediment discharge of 1.8×10^{13} kg yr^{1} (ref. 7)
Use of three significant figures in intermediate calculations is merely to avoid roundoff errors in tabulated values.

As can be seen in Table 2, the agreement between the trace metal residence times based on stream flow and sedimentation rate is, with the exception of those for Cd, quite good and certainly better than other recent comparisons[10,14]. Furthermore, the calculated influx of fluvial suspended particulate matter is comparable with the rate of oceanic sedimentation[13]. The discrepancy between the calculated rate of cadmium input to the oceans by rivers and the rate of cadmium sedimentation is too large to be attributed solely to an abnormality in the composition of the St Lawrence River, especially in view of a recent analysis of Amazon River water[11]. It is probable that the sedimentation rate is a more realistic estimate of oceanic throughput than river input in this case but some re-examination of both the extent of nearshore precipitation and the Cd distribution in marine sediments seems warranted. Co and Ni are the only elements for which the stream flow residence times are greater than the sedimentation rate residence times. This suggests that other forms of input are more important for these elements than the others. It is interesting that when the relative metal contents of terrigenous rock and corrected river flux are compared, Co and Ni are the only elements which are enriched in terrigenous rock. Dry atmospheric fallout may, therefore, be more important for Co and Ni than for the other elements.

Overall, our estimates of residence time are generally shorter than values given in previous compilations[15,16]. This feature is most pronounced in the cases of Fe and Mn. Labeyrie *et al.*[17] have estimated, on the basis of weapon-produced ^{55}Fe settling rates, that the residence time of Fe is about 10 yr. We are thus not alone in proposing such a short residence time for this element. Concern has often been expressed about the difficulty of rationalising residence times much shorter than oceanic mixing times with evidence for the relatively homogeneous distribution of the same elements in ocean sediments. This conflict will be reconciled if biological activity and horizontal dispersion/mixing of both particulate and dissolved metals is sufficient to ensure reasonably uniform metal concentrations in surface waters beyond the continental shelves. Settling of the inorganic and refractory biogenic components of the uniformly distributed particulate matter will then account for the relatively uniform distribution of the metals in the sediments. The residence time of Fe in the surface layer of the open ocean, calculated according to the method of Goldberg *et al.*[16] and using data from the western North Atlantic[9], is 16 yr compared with 20 yr for water. Mn, unlike most other metals, has a concentration in the surface layer which exceeds that in deep waters[9]. This suggests that its surface layer residence time is comparable with that of water. Thus it is likely that both these metals will exhibit fairly uniform distributions in open ocean surface waters despite their short oceanic residence times. The overall residence time of Fe corresponds to a settling rate of 4×10^{-6} m s^{-1} compared with 10^{-5} m s^{-1} for particles containing ^{55}Fe (ref. 17). The equivalent Stokes particle size for inorganic detrital material is about 3 μm. Nevertheless, the primary host for downward transport of Fe in the open ocean is likely to be larger, lower density, biogenic particles, such as faecal pellets, with similar settling velocities.

Metals which remain predominantly in solution are removed from the water column considerably more slowly. Their distributions in the surface layer are probably controlled by mixing and metal incorporation into the biological components that are largely regenerated in the mixed layer. The deep water dissolved metal concentrations will be maintained by the degradation and dissolution of biogenic detritus and the balancing accumulation of metals on to exposed inorganic particle surfaces in the water column and in the sediments. The residence times of the predominantly dissolved metals, therefore, probably represent the time scales in which organic scavenging, biogenic particle settling and dissolution, and final association with inorganic particulate surfaces in the deep water are occurring.

DNA arrangement in isometric phage heads

W. C. Earnshaw
Department of Biology, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

S. C. Harrison
Gibbs Laboratory, Harvard University, Cambridge, Massachusetts 02138

DNA is wound tightly into phage heads in such a way that it tends to form layers concentric with the rigid protein shell. In P22 and wild-type lambda, DNA completely fills the internal volume, with a highly uniform local packing of adjacent segments; in lambda deletion mutants containing less than a full genome, the local packing distance increases correspondingly.

DETERMINING the packing geometry of nucleic acid in virus particles presents a rather difficult experimental problem. In the heads of double-stranded DNA-containing bacteriophage, such as λ or P22, the nucleic acid is condensed 250-fold, and DNA strands are then so closely packed that conventional electron-microscopic techniques have yielded no interpretable images. Moreover, such phages are too large for application of the X-ray diffraction methods used to visualise single-stranded RNA in tobacco mosaic[1] and tomato bushy stunt viruses[2]. A large number of indirect approaches have been tried (see ref. 6), but virtually the only direct data bearing on the problem of DNA arrangement are those of Richards *et al.*[3], who managed to visualise gently disrupted bacteriophage particles in the electron microscope. They concluded that DNA

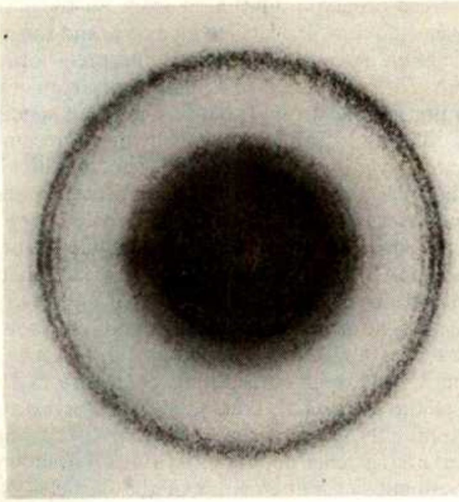

Fig. 1 X-ray diffraction from phage P22. The outer set of rings corresponds to the 25 Å diffraction discussed in the text and shown as a scan in Fig. 2. The experimental conditions are described in ref. 4.

is coiled into the phage head—either coaxially like thread on a spool or with random direction like a ball of yarn. Recent small-angle X-ray scattering studies of intermediates in the P22 head-assembly pathway led us to recognise evidence for considerable long-range order in packaged DNA[4]. We describe here an extension of that work, leading to some conclusions about the organisation of DNA in bacteriophages with isometric heads—P22, λ and T7.

Diffraction from phage

A photograph of X-ray diffraction from a solution of phage P22 is shown in Fig. 1. The series of rings at small angles can be interpreted in terms of the radial distribution of density in the particle[4]. They show that in first approximation, the P22 particle diffracts like a uniformly filled sphere. The strong outer band, corresponding to a spacing of about 25 Å in the structure, is due to DNA[4,5]. A densitometer trace of the intensity in this band is shown in Fig. 2. The diffraction is modulated by a series of ripples, having a periodicity approximately equal to the reciprocal of the head diameter. Experiments with other isometric phages (various strains of λ, T7) show this modulation to be not a mere superposition of other diffraction but rather a consequence of the geometry of DNA packing. Details of the interpretation of these observations are presented below. At wider angles, the diffraction from P22 and λ phage heads show the characteristic B-form DNA pattern, with maxima near 12, 8 and 3.4 Å (ref. 4).

Organisation of phage DNA

The diffraction from phage DNA *in situ*, just described, reveals both local and long-range order in the phage head. The presence of local order, indicated by the strong 25-Å diffraction, ha sbeen recognised for some time[5,6]; the long-range order, indicated by the rippled modulation of this diffraction, was observed more recently by Earnshaw *et al.*[4], who first examined isometric phage with X-ray cameras of sufficient resolution.

Local order: adjacent segments of the DNA molecule are packed in a locally parallel array, with a side-to-side spacing that can be determined from the position of the 25-Å diffraction band[4]. From the width of this band, we can conclude that this spacing is quite uniform throughout the phage head with an 'apparent domain size' of −125 Å (refs 4, 5, 16). Assuming hexagonal packing, as in concentrated gels of DNA *in vitro*[7], the interhelix distance is equal to 1.16δ where δ(~ 25 Å) is the spacing of the observed diffraction (Fig. 4 and Table 1, where the precise determination of δ from the pattern is described). We can also calculate the area of the local 'unit cell' (Fig. 4)—the cross-sectional area occupied by one DNA strand—this area, multiplied by the length of the P22 DNA molecules, gives the volume, *V*, taken up by the packed DNA. This calculated volume is in fact equal to the internal volume of the wild-type phage head, accurately determined from the structure of empty heads[4]. These calculations are summarised in the top line of Table 1.

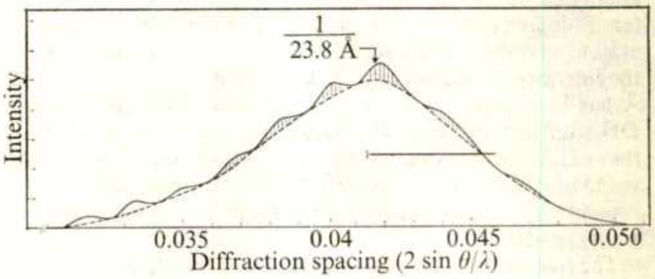

Fig. 2 Densitometer trace in the 25-Å region of a film similar to the one shown in Fig. 1. The film was scanned as described in ref. 4. The shaded peaks are those used for fitting the model in Fig. 3. The horizontal bar indicates the half-width at half-height, 0.004 Å^{-1}. The data have been corrected by subtracting a smooth background due to diffuse scatter of the X-ray beam.

Long-range order: the ripples that modulate the intensity of the 25-Å diffraction have a wavelength of about 1/540 Å, that is, approximately the reciprocal of the internal diameter of the phage head. This indicates coherent diffraction from opposite sides of a particle: locally ordered DNA segments on one side must be diffracting with a fixed phase relative to locally ordered segments on the other. A linear DNA molecule

Table 1 Measured and calculated dimensions for DNA packing in phage heads*

Phage		*d* (Å)	δ (Å)	*A* (Å^2)	*l* (Å)	*V* (Å^3)	*r* (Å)	r_0 (Å)	*n*	*f*	ref.
P22		24.2	23.8	638	14.0×10^4	8.9×10^7	278	278	4(+1)	72	8

λ+	(100)	24.0	23.6	647	16.1	10.4	292	294	5	80	9
λ att^2	(105)	23.5	23.2	625	16.8	10.5	293	294	4	74	10

**d*, mean Bragg spacing of DNA diffraction band measured from films; δ, interlayer spacing, derived from *d* by applying an approximate intensity-profile correction to account for the fact that the intensity maximum will be somewhat displaced from the reciprocal of the spacing between shells; *A*, area of local unit cell of DNA segment packing (cell assumed hexagonal, so that $A = 1.16\,\delta^2$); *l*, length of DNA; *V*, volume occupied by DNA in head ($V = A.l$); *r*, minimum radius to which DNA must extend, calculated from $V = (4/3)\,\pi r^3$; r_0, radius of DNA-protein boundary, calculated from best fit in Fig. 3 by adding 12 Å to the mean radius of the outermost DNA shell; *n*, number of DNA shells used for best fit to diffraction data (Fig. 3), in P22, a protein shell has also been included; *f*, fraction of total DNA in coherently scattering shells; ref. reference for DNA molecular weight.

The number in parenthesis after the name of the lambda phage strain indicates the percentage of wild-type DNA complement present. The genotype of λatt^2 was i^{21}.b515.b519.int$_2$.xis$_4$.att^2.bio$^+$.uvrB$^+$; all other λ strains were s7 (lysis-defective). Diffraction measurements were recorded from λ in 0.05 M NaCl, 0.1 M Tris-HCl (*p*H 7.4), 0.001 M $MgCl_2$ and from P22 in 0.01 M Tris-HCl (*p*H 7.5), 0.005 M $MgCl_2$.

is not likely to form a single crystal inside a spherical phage head (for example, the recent demonstration by Lerman *et al.* of the absence of chain-folding in ethanol-precipitated DNA[19]). Coherence across the phage particle must, therefore, be imposed by the regular, isometric protein shell within which the DNA is contained. Indeed, we would expect segments of the DNA molecule, locally parallel and tightly packed against the inner surface of the phage head, to fall into layers spaced regularly inward from the protein boundary. A spherically averaged picture of the particle will thus show distinct shells of density concentric with the protein shell itself. From the degree of local order implied by the intensity profile, we expect to see three or four such shells before packing irregularities destroy the uniformity of their diameter (Fig. 4). The same mode of packing continues at smaller radii, but packing faults become increasingly frequent.

The calculation presented in Fig. 3 shows that the ripples modulating DNA diffraction from P22 can indeed arise from a shell-like density fluctuation in the particle. The calculation assumes that n-concentric DNA layers, differing in radius by increments of δ, are packed within the protein shell. This relatively tight shell[4] also contributes to the X-ray scattering since its inclusion in the calculation as a shell 24 Å from the outermost DNA layer improves the fit in Fig. 3. The radius of the outermost layer of DNA, 266 Å, has been chosen to achieve the best fit to the observed intensity profile. The radius of the boundary between DNA and protein, denoted r_0 in Fig. 4 and Table 1, can then be taken as this shell radius plus 12 Å (an estimate of the ionic radius of the DNA cylinder, see atomic coordinates in ref. 7). The parameters that best fit the intensity profile are $r_0 = 278$ Å and $n = 4$, where $\delta = 23.8$ Å has been determined directly from the mean spacing of the DNA diffraction band. This value of r_0 is, in fact, the same as the radius corresponding to V (the calculated total DNA volume). Likewise, it is in accord with the inner radius of the protein shell, determined by small-angle X-ray scattering from empty heads[4].

The trace in Fig. 2 shows that the ripples modulating the 25-Å diffraction band account for about 15% of the total intensity. Since only one of the three (100) planes in the local hexagonal lattice (marked by arrows in the insert in Fig. 4) will contribute to this sampled diffraction, we expect the ripples to account for a maximum of one-third of the integrated intensity (actually somewhat less, since the outer layers account for only about 75% of the DNA molecule). Irregularities in the lattice and layer spacing will fill in the minima between ripples, so that the observed ratio of sampled to diffuse intensity is consistent with the picture drawn in Fig. 4. Note, that the envelope of the rippled intensity follows the diffuse diffraction: the local order is essentially the same in all directions, but the packing boundary imposed by a rigid head leads to a long-range radial regularity.

Deletion mutants of phage λ

We have interpreted the diffraction from P22 phage DNA *in situ* in terms of locally parallel segments of DNA, packed tightly into the head in such a way that the polymer tends to form layers concentric with the outer protein shell. This model is summarised diagrammatically in Fig. 4. Further evidence for such a picture comes from measurements on a series of deletion mutants of bacteriophage λ. Unlike P22, which packages a constant headful of DNA, λ packages only the DNA between two distinct sites on the viral chromosome. As a result, genetic deletions result in production of phage heads containing less DNA. We have, in this way, obtained diffraction from structures with varying amounts of DNA packed into a head of constant size. The parameters of the model described above for P22 should be determined in a uniform way for the entire series of measurements on λ deletions: r_0 should be the same for all these structures, since it is in effect determined by the inner radius of the protein shell, and d should be given by the mean spacing of the DNA diffraction band, as before. Our ability to fit the observed diffraction from all the stains by a simple n-layer model, with a single value of r_0 and the measured δ for each deletion, is a strong test of this interpretation.

The results of diffraction measurements from various λ deletion strains are shown in Table 1. The mean spacing, d, of the DNA diffraction band increases with decreasing DNA content, but its half-width does not change. This indicates that the distance between adjacent segments of the DNA molecule increases, but that the uniformity of packing remains essentially the same. In other words, the degree of local order is as great in b221 as in wild-type λ, even though the total length of DNA in the head has decreased by 22% and the average spacing between adjacent segments of the molecule has increased by 9%. As shown by the calculation of V, the increase in mean intersegment spacing compensates for about two-thirds of the lost DNA, that is, V decreases by about 7% when the total DNA content decreases by 25%. This result implies that in the deletion mutants a small fraction of the DNA—presumably near the centre of the particle—is packed more loosely than the rest.

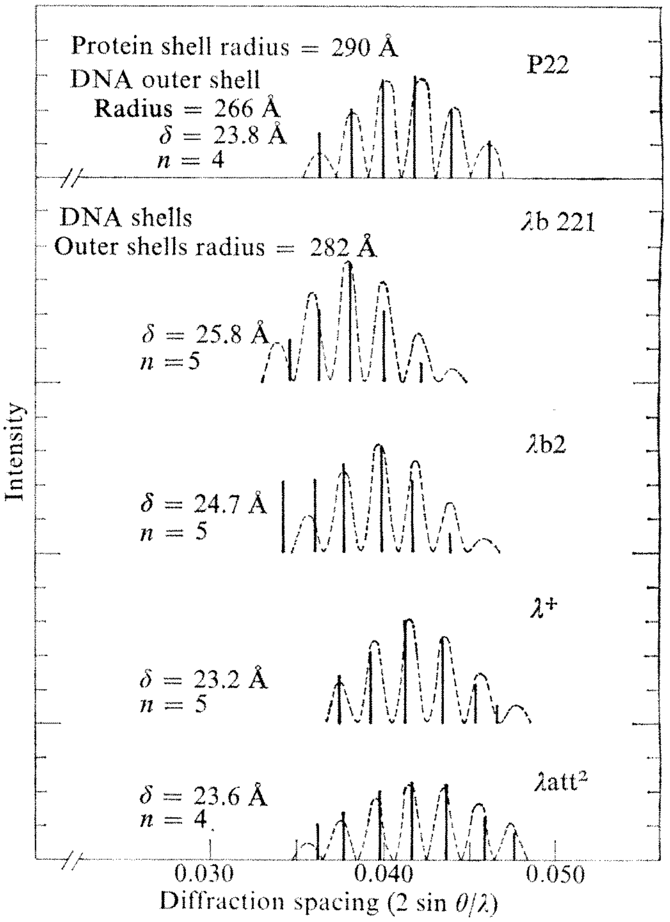

Fig. 3 Correspondence of model calculations to observed diffraction for phage 22 and various λ mutants. Spikes represent position and scaled height of intensity maxima (shaded ripples in Fig. 2); – – – – shows scattered intensity calculated for a series of concentric shells[16], with each shell weighted according to the amount of scattering material it contains. The calculated intensity equals F^2, where

$$F = \sum_{i=1}^{m} 4\pi r_i^2 \left(\frac{\sin 2\pi r_i s}{2\pi r_i s}\right)$$

and r_i is the radius of the ith shell (m in all) and $s = 2\sin\theta/\lambda$, the diffraction spacing. There are n shells of DNA spaced δÅ apart, and in the case of P22 a shell for protein has also been included. For λ mutants, where head size is constant, we have assumed a fixed radius of 282 Å for the outer DNA shell: to obtain r_0, the DNA-protein boundary, 12 Å must be added to this figure.

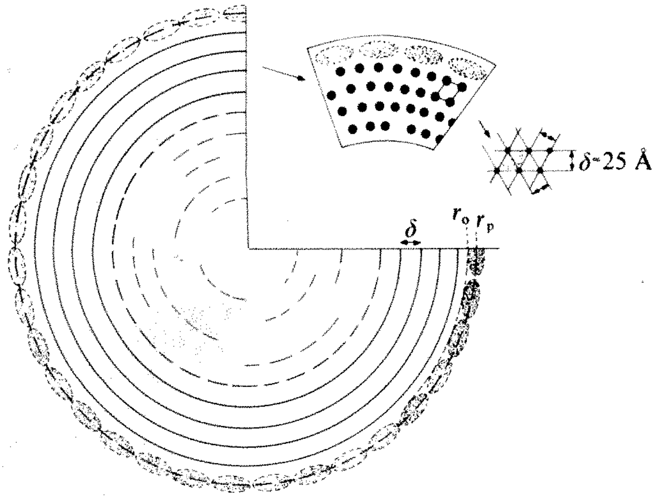

Fig. 4 Diagrammatic representation of the model used to obtain curves in Fig. 3. The protein (radius = r_p) is shown stippled; the radius of the DNA-protein boundary is r_0; the inter-shell spacing is δ. Adjacent segments of the DNA helix are parallel, with the local unit cell assumed to be hexagonal[7,19]. If this is the case, packing faults must be introduced in inner shells, as shown. For this reason, the innermost DNA is shown as partially organised shells, though it could be packed in some other manner. For phage P22 the model includes a shell at radius r_p and four inner shells with spacing δ. For the λ mutants the model includes five shells with spacing δ, the outer shell at a radius of 282 Å.

All strains studied show the same rippled modulation of the DNA diffraction described above for P22. The spacing between these ripples remains essentially constant with varying DNA content, but the positions of the maxima and minima shift, as indicated in Fig. 3. The results in Table 1 and Fig. 3 show that we can fit all observations by models with four or five coherently scattering layers, without changing r_0. That is, we can imagine an outer layer of DNA segments, packed tightly against a protein shell of fixed size, and successive layers of segments packed against the first with a spacing that increases with decreasing DNA content. Moreover, the best value of r_0 for all strains agrees well with the inner radius of urea-treated A^-petit λ, an *in vitro* analogue of empty heads (Earnshaw and Hendrix, in preparation). In contrast with P22, the protein shell itself does not appear to contribute to the 25 Å diffraction, and it has not been included in the model calculation.

The fraction of the DNA molecule that would be contained in these coherently-diffracting layers varies from about 90% for b221 to about 75% for att[2] (Table 1). In all cases, then, a large fraction of the molecule is packed in this way. There are probably several further layers, but at this distance from the constraining walls of the phage head, the segments would be sufficiently out of register that they would not contribute to ripples in the 25-Å diffraction.

The results from λ strains in Table 1 refer to phage in 0.05 M NaCl, 0.01 M Tris (*p*H 7.4), 0.001 M $MgCl_2$. Substitution of 0.01 M polyamine (spermidine or putrescine) for Mg^{2+} has no effect on the measured spacings. Moreover, diffraction from intracellular λb2.s7 accumulating in unlysed su^- cells shows the 25 Å band quite clearly. We conclude, as we did earlier for P22[4], that the arrangement of DNA in a phage head does not change when lysis alters its ionic environment. Polyamine may, however, be important for the initial packaging event[11].

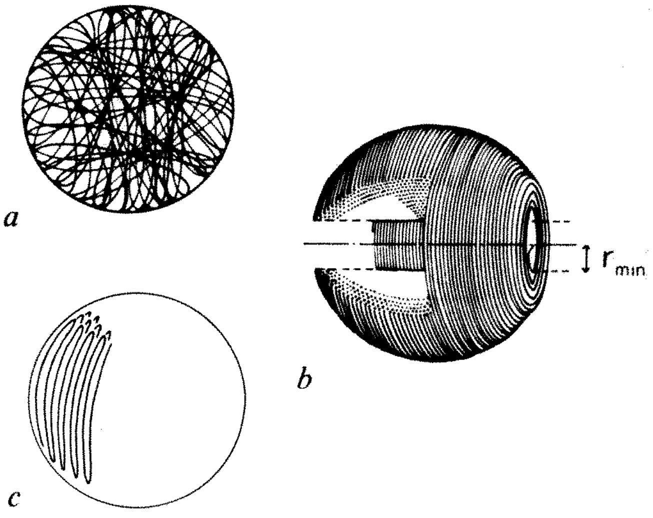
Three dimensions

What more detailed pictures of DNA packing are consistent with the picture presented above? The electron micrographs of gently-disrupted phage heads obtained by Richards *et al.*[3] show unexpanded DNA bundles, flattened into the grid: DNA strands near the periphery of these bundles always have a circumferential orientation. These micrographs suggest that DNA is not folded with sharp kinks inside the phage head, but rather, that it is wound with relatively uniform curvature. Richards *et al.*[3] proposed two limiting descriptions of DNA in phage heads based on these images: a 'ball of string' and a 'concentric spool'. In the first (Fig. 5*a*), DNA is wound roughly along a great circle path at any radius, with no particular relation of the tilt of the planes of successive great circular windings. In the second (Fig. 5*b*), the molecular windings are concentric with a single axis. Our observations seem to be inconsistent with the ball-of-string picture. The crossing of successive turns in a ball of string does not lead to parallel adjacent strands or to radially concentric layers. Such crossing also leaves gaps too large to be compatible with the tight packing of DNA in the head. Coaxial winding does not present these difficulties: segments are locally parallel and closely packed. Our data do not specify the relative orientation of these windings and the axis of the phage tail.

Certain folded structures might also be consistent with an overall organisation into shells of DNA segments layered inward from the protein, provided that the folds were appropriately positioned (Fig. 5*c*). Folds could plausibly result only from interaction of DNA with specific sites on the inner surface of protein subunits. The continuous variation of DNA spacings observed in λ deletions is difficult to reconcile with a fixed set of folding positions. Moreover, the local symmetry of the protein surface lattice implies that only radially-directed DNA can have an equivalent orientation with respect to each folding site: the uniformity of packing we have observed rules out a radial direction. Finally, we would not expect folded structures, when flattened on to an electron microscope grid, to show the images of coiled, circumferentially-directed strands seen by Richards *et al.*[3]. For these reasons, we prefer the coiled structure shown in Fig. 5*b*.

In any structure with more or less uniformly bent DNA, the stiffness of the polymer will prevent windings of very small radius, leaving a roughly cylindrical cavity in the centre of the head (Fig. 5*b*). Changes in packing of DNA in this region—estimated below to be less than 10% of the total volume of the head—might account for the slight decrease in *V* with decreasing DNA content. This could also account for the region of low density seen in the centre of λ and λ*dg* in ultra-thin sections in the electron microscope[18]. A reasonable value for r_{min}, the radius of the cylindrical cavity, is the radius of a circle of DNA for which the bending enthalpy equals ~ 7 kcal mol^{-1}—an estimate for the enthalpy of a single 180°

Fig. 5 Schematic representation of various models discussed in the text. *a* Ball-of-string. *b* Coaxial spool. *c* Chain-folded structure (with 180° folds at each end).



fold[12]. The bending enthalpy of DNA was determined by Gray and Hearst[13]: their figure of $\Delta H_{\mathrm{bend}} = 75$ kcal Å mol^{-1} rad^{-2} is applicable, strictly speaking, only to radii of curvature comparable with the solution persistence length ($\sim$ 500 Å), but its use with rather smaller radii seems adequate, since even for $r = 50$ Å the bend is only about 4° per base pair. With this value for ΔH_{bend}, we get $r_{\mathrm{min}} \sim 60$ Å. Also, using this estimate of r_{min}, integration over the total occupied volume yields $\Delta H_{\mathrm{tot}} = 4\pi(\Delta H_{\mathrm{bend}}/A))(r \ln(2r_0/r_{\mathrm{min}} - \frac{1}{2}) - r_0 + r_{\mathrm{min}}/2) \sim 500$ kcal (where A and r_0 taken here as 647 Å^2 and 294 Å, appropriate for λ, are defined in Table 1 and Fig. 4). To fold DNA into a λ head would require more than $l/2r_0$ folds (l is the DNA length; $2r_0$, the head internal diameter)—more than 2,000 kcal. The cylindrical cavity defined by r_{min} contains about 9% of the total volume. The column V in Table 1 shows that in λb221, only about 91% of the total volume inside $r_0 = 294$ Å is required for DNA packed with spacing $\delta = 25.8$ Å. In this extreme deletion, then, the central regions might actually be nearly free of DNA. In other forms, a larger fraction of the total volume is required (all of it in wild type and att[2]). In these structures, most of the DNA can be coiled into cylindrically concentric shells, but up to 10% might be folded back and forth lengthwise in the central region (a possibility suggested to J. Schellman), perhaps passing from there to the phage tail (see cross-linking experiments with λ and other phages—refs 14 and 15).

We thank Jonathan King for continuing interest and valuable advice and Gerard Bricogne, John Schellman, and R. Kornberg for helpful discussions. Phage samples were gifts of Roger Hendrix (λ b221), Mark Ptashne and Andrea Jeffrey (λb2), William McClure (λ$^+$, T7), Susan Gottesman (λatt^2), and Phillip Youderian (λ n515 b519). We thank Jonathan King and David Botstein for useful criticism of the manuscript. We acknowledge grant support from the National Cancer Institute (to S.C.H.) and from the National Institute of General Medical Sciences (to J. K.), an NSF Predoctoral Fellowship (to W. C. E.), and a PHS Research Career Development Award (to S.C.H.).

Initiation of chick cell division by trypsin action at the cell surface

Darrell H. Carney & Dennis D. Cunningham

Department of Medical Microbiology, College of Medicine, University of California, Irvine, Irvine, California 92717

Trypsin immobilised on polystyrene beads causes initiation of cell division which cannot be accounted for by trypsin released into the medium or into the cells. Also, initiation by soluble trypsin is inhibited by immobilised soybean trypsin inhibitor. These results demonstrate that trypsin can initiate proliferation at the cell surface.

THE site of action of peptide hormones and certain growth factors is often presumed to be at the cell surface. Indeed, binding studies and isolation of binding proteins by affinity chromatography have demonstrated that specific receptors for these molecules exist in the plasma membrane. Such receptors might be involved primarily in transport or other functions, however. For example, it has been shown that there are cell surface receptors for steroid hormones even though their site of action is clearly inside the cell[1]. There are reports that certain peptide hormones and growth promoters can act without entering cells [2–6], but most of this evidence has been obtained with Sepharose-immobilised preparations. The validity of these studies has been challenged[7–10] primarily because of the amount of soluble material released[7,8] and because such material may be 'superactive'[10]. Therefore, it is still questionable whether peptide factors can exert their biological effects without entering cells.

Trypsin and certain other proteases initiate proliferation of cultured quiescent chick embryo fibroblasts (CEF) (refs 11–18). This system has two important advantages for studying the mechanisms involved in initiation of cell proliferation. First, the initiation occurs in serum-free medium without additional growth factors[13], and second, it is caused by purified agents with well characterised proteolytic activities. In spite of these advantages, little progress has been made towards elucidating the actual mechanisms involved. It has been reported that 5-min treatments with soluble proteases or proteases linked to Sepharose beads doubles the number of mouse 3T3 cells[19–21]. This would suggest that trypsin acts at the cell surface. But other investigators have not achieved significant initiation of 3T3 cell division with trypsin using various experimental conditions including exposures of up to several days[17, 22, 23]. Even in chick cells, whose division is readily stimulated by trypsin, the protease must be present for at least 2 h to cause a significant increase in cell number, and the fraction of cells which respond increases with length of exposure up to 24 h (refs 17, 18). Such lengthy exposure times suggest a more complex mechanism of initiation than the simple binding or cleavage of specific receptors. Indeed, it has not been possible to correlate cleavage of specific surface membrane proteins with initiation of proliferation by proteases[14–16, 24]. Moreover, both thrombin (ref. 25 and B. M. Martin and J. P. Quigley, personal communication) and trypsin[26] accumulate inside cultured cells after exposures sufficient to initiate cell division. These considerations prompted us to develop techniques to rigorously determine if trypsin could initiate proliferation of chick fibroblasts without entering the cells.

We report here that trypsin covalently attached to poly-

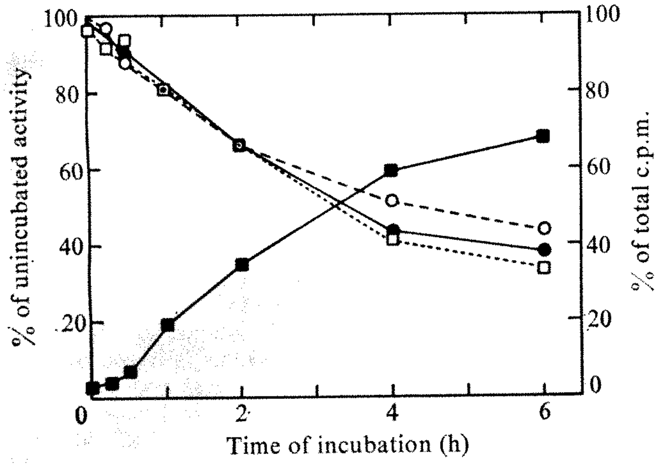

Fig. 1 Autodigestion of ^{125}I-trypsin. Correlation between TCA-precipitable radioactivity (c.p.m.), tryptic activity, and mitogenic activity. Trypsin, iodinated with Chloramine T (65,000 c.p.m. μg^{-1}), was incubated at 37 °C in PBS (*p*H 7.4). After the indicated times, aliquots were removed and assayed for acid-soluble (■) and precipitable (□) radioactivity (5% TCA), for proteolytic activity (●) as determined by hydrolysis of *p*-toluene-sulphonyl-L-arginine methyl ester[33], and for mitogenic activity (○) on quiescent CEF as described in Table 1. When compared with unlabelled trypsin, the ^{125}I-trypsin used in these experiments retained all of its mitogenic and proteolytic activity. In addition, the loss of these activities followed the loss of TCA-precipitable radioactivity. These observations show that ^{125}I-trypsin molecules are active and representative of both labelled and unlabelled molecules.

styrene beads initiates proliferation of secondary CEF. Results from various experiments have demonstrated that this initiation is not caused by trypsin released from the beads. In addition, we report that soybean trypsin inhibitor (SBTI) attached to polystyrene beads can inhibit the proliferative effect of cell-associated trypsin even if added 4 h after the cells have been exposed to initiating levels of the protease.

Immobilised trypsin preparations

In searching for a stable form of immobilised trypsin, we first tried two commercially available preparations, trypsin–Sepharose (Worthington), and trypsin–acrylamide (Sigma). Addition of optimal amounts of either preparation to quiescent CEF resulted in population doublings after 24 h. But, a cell number increase nearly as large was achieved either with medium from which the beads had been removed, or with the beads physically separated from the cells by nylon nets during the 24 h incubation. This demonstrated that the observed initiation resulted largely from released trypsin. In contrast to the above preparations, trypsin linked by carbodiimide condensation to carboxylate-modified polystyrene beads initiated division of only about half of the cells. Medium from which these beads had been removed did not initiate CEF, however, suggesting (1), that the linkage was relatively stable and (2), that the observed initiation was due to trypsin still attached to the beads. We therefore used polystyrene bead preparations for all of the following experiments.

Active component of polystyrene-immobilised trypsin

Table 1 shows results from a representative experiment which demonstrated that initiation of CEF by trypsin-beads was due to trypsin and not the polystyrene beads or a 'nonspecific' protein-bead complex. Addition of 50 μg of trypsin-beads (~ 225 beads per cell) to quiescent fibroblasts resulted in a 32% increase in cell number over control populations by 24 h. In contrast, the same amount of protein-free beads or beads with bovine serum albumin (BSA), ovalbumin, or SBTI attached did not significantly increase cell number over controls. This specificity was also observed over a wide range of bead concentrations.

Coverslip experiments

Our first attempts to determine if initiation by trypsin-beads resulted from trypsin released during incubation involved an approach where two populations of cells, one with and one without beads, shared the same medium. We cultured CEF on small glass coverslips and then added trypsin-beads (~ 225 beads per cell) to some of the cultures. Nearly all of the beads firmly adhered to the cells within 3 h. We then relocated coverslips with and without beads into new dishes. The beads remained tightly associated with the cells both during transfer of the coverslips and during the subsequent incubation. Regardless of the proportion of coverslips with and without

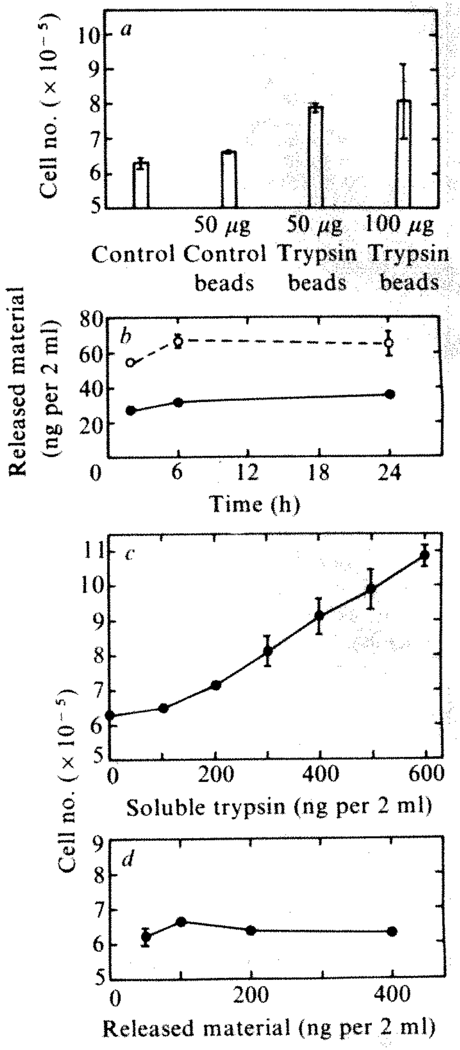

Fig. 2 Amount of material released from trypsin-beads during incubation with CEF and the mitogenic effect of different amounts of trypsin–beads, soluble trypsin, and released material. ^{125}I-trypsin (described in Fig. 1) was covalently attached to polystyrene beads as described in Table 1. 50 μg and 100 μg of the ^{125}I-trypsin-beads were added to quiescent CEF (Table 1). *a*, Cell number 24 h after bead addition. *b*, Amount of TCA precipitable material released into the medium from 50 μg (●) and 100 μg (○) of ^{125}I-trypsin-beads during the 24 h incubation. In the same experiment indicated amounts of soluble trypsin (*c*) and material released during the 2-h preincubation of ^{125}I-trypsin-beads (*d*) were added to cultures of quiescent CEF and the cell number counted 24 h later. The absence of an error bar means it was smaller than the symbol. Before using TCA precipitable radioactivity as a measure of the accumulated mitogenic activity, it was necessary to determine if material released from the beads was degraded to TCA soluble material during incubation. 0.5 μg of soluble ^{125}I-trypsin added to CEF cultures remained TCA precipitable during a 24-h incubation. Therefore, it is unlikely that material was released in an active TCA-precipitable form and then degraded.

Table 1 Effect of bead preparation on CEF cell number

Addition	Cell number ($\times 10^{-5} \pm$ s.d.)	% Increase over control
None	6.28 ± 0.30	
Beads alone	6.27 ± 0.02	−0.2
BSA-beads	6.48 ± 0.28	3.2
Ovalbumin-beads	6.56 ± 0.06	4.5
SBTI-beads	6.51 ± 0.24	3.7
Trypsin-beads	8.32 ± 0.16	32.5

Secondary chick embryo fibroblasts, obtained as described by Rein and Rubin[31], were seeded at 5.5×10^5 cells per 35-mm dish in 2 ml of medium 199 containing 2.0% Tryptose phosphate broth and 2% chicken serum. After 4 h the medium was changed to medium containing 0.02% chicken serum. After 48 h, 50 μg of beads alone or beads with the indicated proteins attached were added to the quiescent cultures and cell number was determined 24 h later. The data in all tables and figures are means of duplicate determinations. Trypsin-beads were prepared as follows: 500 μg of trypsin (three-times recrystallised, Worthington) was mixed with about 5 mg of carboxylate-modified polystyrene beads (0.926 μm diameter, Dow Diagnostics) in 0.1-M sodium acetate, *p*H 6.0, and linked by addition of water soluble carbodiimide (1-cyclohexyl-3(2-morpholinoethyl)-carbodiimide metho-*p*-toluene sulphonate, Sigma) to 0.1 M (ref. 32). After 4 h of stirring at 4 °C the beads were *a*, washed five times by centrifugation (10,000*g* for 10 min) through the sodium acetate buffer; *b*, pre-incubated at 37 °C for 2 h in conditioned medium (taken from CEF cultures 40 h after changing to 0.02% serum medium), and *c*, washed and resuspended in 2.5 ml of phosphate buffered saline (PBS). 50 μg of these beads (1.2×10^8 beads) had approximately 2.0 μg of trypsin attached. All other protein-beads were prepared as described for trypsin. During the above 2 h pre-incubation there was considerable release of trypsin-derived material. Therefore, we always included this pre-incubation to minimise the amount of material released when beads were added to CEF.

beads in any single dish, we found a 50% increase in cell number after 36 h on coverslips previously overlaid with trypsin-beads, but no increase in cell number on coverslips without them. Moreover, the amount of initiation observed in bead-contacted cells was not decreased by doubling the volume of the medium. Because initiation of CEF is very sensitive to changes in soluble trypsin concentration (see Fig. 2*c*), these experiments strongly suggested that released trypsin was not responsible for the initiation observed with trypsin-beads.

Measurement of released material and assessment of its activity

To quantitate the release of trypsin from beads during incubation, we attached ^{125}I-trypsin to polystyrene beads as described in Fig. 2. When these trypsin-beads were added to CEF, a small amount of material was released into the medium. Therefore, it was important to determine if the released material was intact trypsin and if it retained mitogenic activity. When fractionated on Sephadex G-75 columns, only a small portion of the released material was intact trypsin (23,000 molecular weight). The majority was peptide fragments with molecular weights of 12,000 or less. To determine if this material was active necessitated a very sensitive measure of mitogenic activity. Fortunately, we observed that during autodigestion of ^{125}I-trypsin the loss of mitogenic activity (as well as proteolytic activity) closely followed the decrease in trichloroacetic acid (TCA)-precipitable radioactivity (Fig. 1). Thus, simply measuring the TCA-precipitable radioactivity released from ^{125}I-trypsin beads during incubation with CEF indicated the maximum amount of released mitogenic activity.

Figure 2 shows representative experiments which demonstrated quantitatively that the amount of material released from trypsin-beads could not account for the observed initiation of cell division. The addition of 50 μg of trypsin–beads to quiescent CEF cultures resulted in a 25% increase in cell number over controls by 24 h (Fig. 2*a*). During this 24 h incubation 35 ng of TCA precipitable material was released into the medium (Fig. 2*b*). It is clear that this 35 ng of released material could not account for the initiation, since addition of 100 ng of soluble trypsin had virtually no effect on cell number by 24 h (Fig. 2*c*). In fact, to cause a 25% increase in cell number would require approximately 280 ng of soluble trypsin (Fig. 2*c*). Thus, even if all of the released TCA-precipitable material were active, eight times more would be required to account for the initiation observed with 50 μg of trypsin-beads. Addition of 100 μg of trypsin-beads brought about no additional increase in cell number even though twice as much material was released into the medium (Fig. 2*a*, *b*). It is noteworthy that adding up to 400 ng of released material had no effect on cell number within 24 h (Fig. 2*d*). Thus, even at high concentrations released material was not able to initiate CEF.

Can trypsin be released from beads directly into CEF?

The above experiments ruled out the possibility that release of trypsin into the medium caused the observed initiation. Another possibility, however, is that active trypsin could be released directly into the cells without appearing in the medium. We attempted to examine this possibility by incubating CEF with ^{125}I-trypsin-beads, separating the beads and cells, and determining if any radioactivity remained with the cells. In these experiments, however, we were unable to separate most of the polystyrene beads from the surface of intact cells by treatments with trypsin, hyaluronidase, neuriminidase, collagenase, or low concentrations of detergents. Therefore, we rinsed the cells, dissolved them in sodium dodecyl sulphate (SDS), collected the beads on Millipore filters, and measured the amount of radioactivity on the filters and in the filtrate (Table 2). As shown, soluble trypsin passed through the filters while trypsin attached to the beads was retained. SDS treatment alone caused the release of an average of 2.6% of the bound radioactivity, but no additional soluble radioactive material was observed when the beads were incubated with the cells for periods up to 24 h. These experiments ruled out significant direct uptake of trypsin from the beads by CEF.

Table 2 Recovery of ^{125}I-Trypsin attached to beads

Preparation	Incubation conditions	Soluble radioactivity (c.p.m.)	Bead-attached radioactivity (c.p.m.)	% Recovered on beads
^{125}I-Trypsin-beads (preparation A)	SDS treatment alone	1,035	26,017	96.2
	3 h with CEF	688 ± 61	$19,375 \pm 1,770$	96.6
	6 h with CEF	606 ± 13	$21,099 \pm 3,958$	97.2
	24 h with CEF	209 ± 4	$16,118 \pm 409$	98.7
^{125}I-Trypsin-beads (preparation B)	SDS treatment alone	153 ± 16	$10,895 \pm 1,395$	98.6
	24 h with CEF	151 ± 17	$9,596 \pm 375$	98.5
Soluble ^{125}I-trypsin	SDS treatment with CEF plus control beads	$12,731 \pm 2,023$	527 ± 55	4.0

^{125}I-Trypsin-beads prepared as described in Fig. 2 were added to quiescent CEF (see Table 1). After the stated incubation periods, medium and non-adherent beads were removed, the dishes were rinsed twice with PBS, and the monolayers were dissolved in 1 ml of PBS containing 2% SDS. The beads were then collected on Millipore filters (0.45 μm), the dishes and filters washed twice with PBS, and the filters and soluble material (including washes) counted. As controls, trypsin-beads from each preparation were added to dishes treated with the SDS solution and filtered. In addition, we added soluble ^{125}I-trypsin and ovalbumin-beads to CEF monolayers, immediately dissolved these with SDS, and filtered them. Since soluble trypsin was not retained on the filters in these conditions, it is unlikely that material released from beads during incubation became reassociated with beads or cellular material and was retained on the filters.

Visualisation of bead–cell interaction

When CEF are treated with soluble trypsin or thrombin they undergo morphological changes in addition to their increase in cell number. Such cells appear more elongated and slightly retracted with fewer cell–cell contacts and decreased cytoplasmic spreading[16]. Treatment with soluble trypsin also has been reported to cause the release of a protein of 250,000 molecular weight (the 'LETS' or '250K' protein) from the surface of these cells[14-16, 27]. Figure 3*a* and *b* shows CEF 24 h after addition of 50 µg of trypsin-beads and control phosphate buffered saline (PBS), respectively. Notably, the trypsin-bead-treated cells had altered morphologies resembling that reported for CEF treated with soluble trypsin. In addition, analysis of medium from cells treated with trypsin-beads revealed that a protein of approximately 250,000 molecular weight was released from the cells into the medium. These results indicated that trypsin-beads had a proteolytic effect on the surface of CEF similar to that of soluble trypsin.

Some of the trypsin-beads were endocytosed by CEF during incubation. Figure 3*c* and *d* shows trypsin-beads in contact with and inside of cells. Based on stereometric reconstruction from cross sections of 150 cells[28], we estimated that less than 4 of approximately 225 beads added per cell were endocytosed by 9 h, a time corresponding to the peak of DNA synthesis[11]. It is important to emphasise that of 100 internalised beads observed in cross sections, all appeared to be surrounded by intact membranes (see Fig. 3*d*). Therefore, even if these few internalised trypsin beads were involved in initiation of cell division, they acted on the plasma membrane and did not interact directly with the cytoplasm. Furthermore, the process of bead endocytosis itself did not trigger cell division because ovalbumin-beads, which did not stimulate DNA synthesis or cell division, were also taken up by CEF.

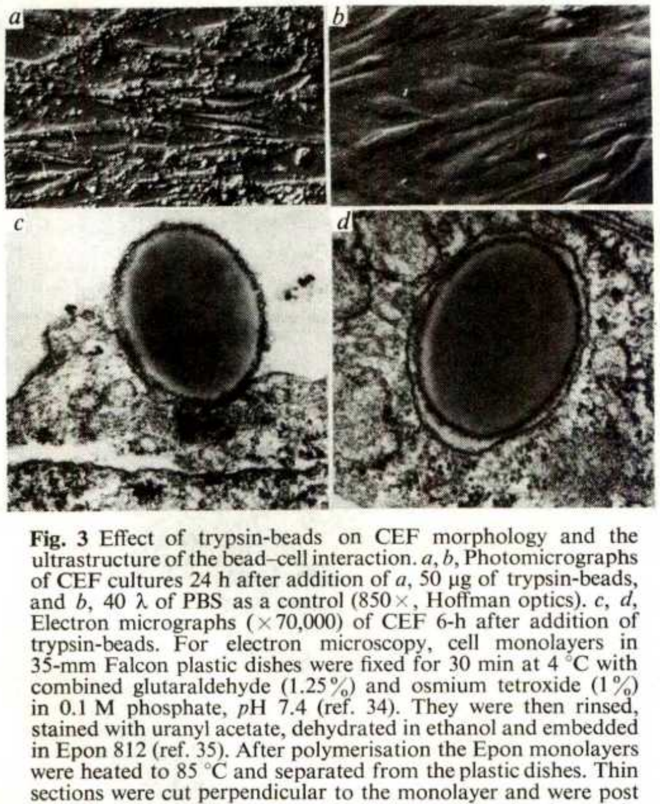

Fig. 3 Effect of trypsin-beads on CEF morphology and the ultrastructure of the bead–cell interaction. *a*, *b*, Photomicrographs of CEF cultures 24 h after addition of *a*, 50 µg of trypsin-beads, and *b*, 40 λ of PBS as a control (850×, Hoffman optics). *c*, *d*, Electron micrographs (×70,000) of CEF 6-h after addition of trypsin-beads. For electron microscopy, cell monolayers in 35-mm Falcon plastic dishes were fixed for 30 min at 4 °C with combined glutaraldehyde (1.25%) and osmium tetroxide (1%) in 0.1 M phosphate, *p*H 7.4 (ref. 34). They were then rinsed, stained with uranyl acetate, dehydrated in ethanol and embedded in Epon 812 (ref. 35). After polymerisation the Epon monolayers were heated to 85 °C and separated from the plastic dishes. Thin sections were cut perpendicular to the monolayer and were post stained with uranyl acetate and lead citrate. When beads were in contact with the surface of CEF we often observed thickened filamentous material beneath the plasma membrane (note Fig. 3*c*). But, because some beads were observed inside the cells (Fig. 3*d*) such thickenings may be involved in binding or endocytosis and not be related to initiation. That trypsin-beads were endocytosed by CEF was demonstrated by serial sectioning and by using tannic acid–glutaraldehyde as a primary fixative to show that the membranes surrounding the beads were not accessible from outside the cells[36].

Fig. 4 Inhibition by SBTI-beads of cell division initiated by soluble trypsin. Indicated amounts of soluble trypsin were added to quiescent secondary CEF (as described in Table 1). After the indicated periods medium containing trypsin was removed and replaced with conditioned medium taken from unstimulated parallel cultures. 120 µg of SBTI–beads were added to half of the cultures. Cell number was determined 24 h after the beginning of trypsin exposure. The absence of an error bar means it was smaller than the symbol. *a*, Effect of 2-h exposure to stated trypsin concentrations. *b*, Effect of stated exposure times to 1.2 µg of soluble trypsin per 2 ml of medium. Conditioned medium alone (○); conditioned medium plus SBTI-beads (●). Experiments with ^{125}I-SBTI–beads demonstrated that ~95% of the SBTI remained attached to the beads during incubation with CEF with or without trypsin.

Initiation by soluble trypsin can be inhibited at the cell surface

Assuming that soluble trypsin acts in the same manner as immobilised trypsin and initiates proliferation by action at the cell surface, then it should be possible to inhibit such initiation with a trypsin inhibitor bound to polystyrene beads. Indeed, in early experiments we found that addition of 120 µg of SBTI–beads to CEF inhibited 95% of the cell division initiated by 0.5 µg of soluble trypsin. But, measurements of soluble trypsin in the medium revealed that part of the inhibition could be attributed simply to a decrease in the concentration of soluble trypsin.

To bypass the problem of interpreting changes in the concentration of soluble trypsin, experiments were performed where only cell-associated trypsin was exposed to the SBTI-beads (Fig. 4). In these experiments we incubated CEF with trypsin for periods up to 4 h, and then removed the medium (containing trypsin) and replaced it with conditioned medium alone or conditioned medium plus SBTI-beads. Figure 4*a* shows the effect of 2-h incubations of CEF with various concentrations of trypsin. The highest level of initiation was a 23% increase over control cells with 1.2 µg of added trypsin (0.6 µg ml^{-1}). Addition of 120 µg of SBTI-beads (≈ 680 beads per cell) with fresh conditioned medium after the 2-h incubation with trypsin inhibited this stimulation by more than 80%. Even after a 4-h exposure to trypsin at this concentration, approximately two-thirds of the initiation could be inhibited by SBTI-beads (Fig. 4*b*). The same number of SBTI-beads only slightly inhibited serum stimulation of CEF. Thus, the inhibition was specific for initiation by soluble trypsin at the cell surface. Moreover, addition of ovalbumin beads did not inhibit initiation by soluble trypsin. These results do not exclude the possibility that soluble proteases which accumulate inside cells during long exposures might have a role in initiation of cell division. It is, however, difficult to explain how SBTI-beads inhibited initiation after 4-h trypsin exposures if the primary site of trypin action during this period were not at the cell surface.

Transmembrane action of trypsin and other growth factors

Several growth promoters have been reported to act at the cell surface. For example, there are reports that concanavalin A, phytohaemagglutinin, and pokeweed mitogen initiate DNA synthesis in lymphocytes while immobilised on Sepharose beads or plastic surfaces[5,6]. There is, however, a report that preparations of these mitogens which are active when soluble lose all of their mitogenic activity when immobilised by techniques similar to those used in the earlier reports[9]. Thus, it is uncertain whether these mitogens act at the cell surface or not.

Two other peptide factors immobilised on Sepharose beads have also been reported to act at the cell surface. (1) There are reports that insulin-Sepharose is biologically active[2,3], but recent experiments have demonstrated that all or most of its biological activity can be attributed to released soluble insulin[7,8]. (2) Nerve growth factor–Sepharose has been reported to stimulate neurite extension from sympathetic ganglia[4]. In these experiments, controls were included to measure release from the beads. These controls, however, were indirect and involved diffusion through plasma clots. With such controls it is not possible to exclude release from beads directly into the cells. In addition, the validity of experiments with Sepharose-immobilised peptide factors has been challenged on the basis that incubation of these preparations with proteins can cause release of 'superactive' factors (often with altered specificity)[10]. These problems with Sepharose preparations and the necessity for definitive controls led us to seek a more suitable method for immobilisation and to directly quantitate material released into the medium and into cells.

The experiments we report with trypsin attached to polystyrene beads demonstrate that trypsin action at the cell membrane is sufficient to initiate proliferation of CEF. In addition, the inhibitory effect of SBTI-beads on initiation by soluble trypsin indicates that soluble trypsin can also act at the cell surface to initiate proliferation. It remains to be seen how the mechanism of initiation by trypsin relates to that of other growth factors. It has been suggested that proteases may bind to or cleave receptors for more specific growth factors, and thus mimic their actions[29,30]. If so, the ability of trypsin to initiate CEF by action at the cell surface implies that these growth factors also act at the cell surface.

letters to nature

The binary pulsar observed at four radio frequencies

PSR1913+16 is still the only known pulsar which is a member of a binary stellar system, as such, it offers the possibility of several new investigations into both the nature of pulsars and general relativity. Unfortunately, the pulsar is very weak and previous observations[1,2] have only been made with the 1000 ft telescope at Arecibo at a frequency of 430 MHz. We report here observations at four radio frequencies which show that this pulsar has properties which are similar to those of the other pulsars.

The 250 ft MK IA telescope at Jodrell Bank was used for the observations, in 1975 and 1976, at frequencies of 327, 408, 610 and 1,420 MHz. Dispersion-removing receivers were used at all frequencies providing total bandwidths of 1, 1, 4 and 4 MHz respectively, each of which was divided into 32 equal contiguous sub-bands. The time resolution is then limited either by dispersion within these sub-bands or by the integration bin size used. The integrations were carried out by forming on-line sub-integrations of 5 or 10 min in length, using the orbital ephemeris published by Taylor *et al.*[2]. These sub-integrations were added together later for total periods of between 8 and 12 h, amounting to between 1 and 1½ orbital periods of the binary system. This was achieved using the data reduction technique described by Lyne *et al.*[3], after slight modifications to compensate for the motion of the pulsar in the binary system.

The pulsar integrated profile obtained at each of the four frequencies is shown in Fig. 1 in which the whole of the 59 ms period of the pulsar is represented. The observations were made on different occasions, and have been arbitrarily aligned in phase. In all cases, the profile seems to have two main components whose separation does not vary significantly with frequency. The profile shape is characteristic of many other pulsars, although the profile covers a larger fraction of the pulsar period (~20%) than for the majority of pulsars. An unusual feature is that there does not seem to be any significant broadening of the pulses at low frequencies by scattering in the interstellar medium. Any broadening present amounts to only a few ms at 327 MHz which is rather small for a pulsar having a dispersion measure of 167 cm^{-1} pc (ref. 4).

The spectrum of the pulsar derived from these observations is of some interest and is shown in Fig. 2. There is a certain amount of variability in intensity over timescales of months in some pulsars[5], if such a variation is occurring in PSR1913+16 the measurements in the diagram, being spaced by some months, may have effective errors somewhat greater than the errors of measurement indicated. The spectral index in the range 327 MHz to 1420 MHz is measured as -1.5 ± 0.3 which is typical of many of the other pulsars[6]. Further observations, more closely spaced in time will be required to confirm this value.

Observations are continuing with the aim of examining the evolution of the orbital parameters of the binary system and of studying any associated changes in the intensity and polarisation of the radio emission. In particular, if precision of the pulsar occurs it may be possible to view the pulsar from a different rotational latitude, which is something that is not possible for any other known pulsar.

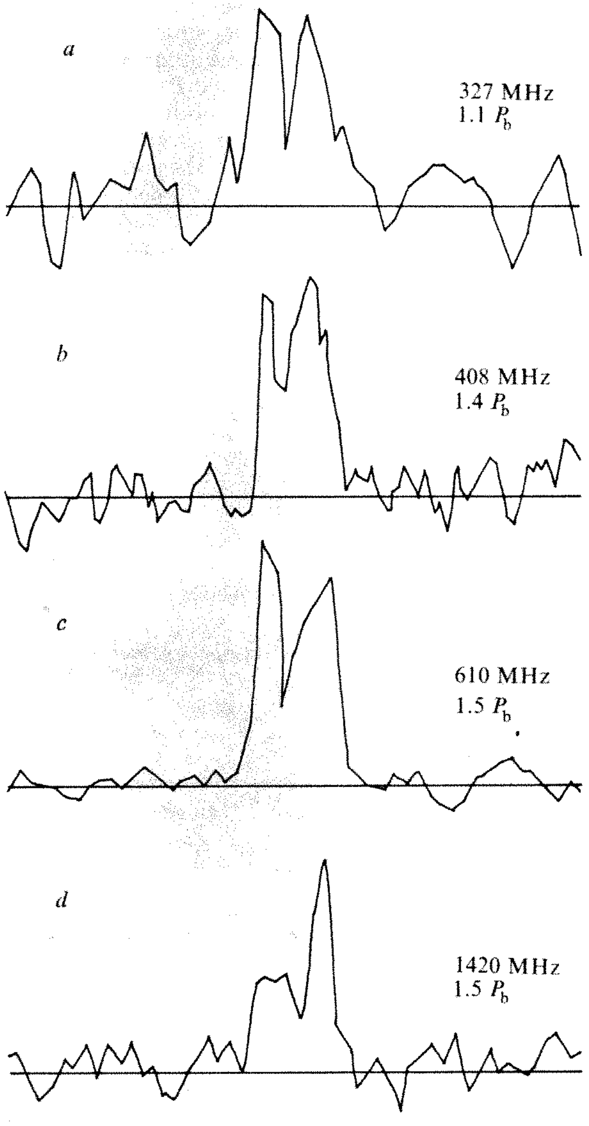

Fig. 1 The PSR1913+16 pulse profile at four radio frequencies. *a*, 327 MHz, February 1976; *b*, 408 MHz, May 1976; *c*, 610 MHz, April 1975; *d* 1420 MHz, June 1975. In each case, the whole of the 59-ms pulsar period is shown. The integration time in terms of the binary orbital period $P_b \approx 7.7$ h is also indicated.

X-ray bursts from dense clouds

X-RAY heating of matter accreting on to a compact object can create unstable flows leading to irregular X-ray emission[1–4]. Previous discussions of this instability have concentrated on the case of spherically symmetrical infall onto a stationary object. The rise-time of X-ray variations is then related to the free-fall timescale from the choking or accretion radius, whichever is relevant. Phenomena due to the presence of a magnetosphere[4] may, however, reduce this estimate. It is not clear that bursts with duty cycles as short as 10^{-3} can arise from the heating instability. Such bursts are observed, and here I investigate the effect of the motion of a compact object through a relatively dense medium. The passage of the compact object through a denser shell, which builds up outside the X ray-heated gas, produces a short burst of X rays. This creates yet another hot region leading to the repetition of bursts on a crossing time. Such behaviour may be relevant to the weak bursts possibly associated with the Cómetary Globule NGC 5367 (ref. 5), and the much shorter timescale luminous X-ray bursts[6], some of which are associated with globular clusters.

Consider first what happens when a neutron star or white dwarf, with velocity v km s^{-1}, accretes from a dense cloud such as NGC 5367. Much of the material is probably in the form of molecular hydrogen of density $n_4 \sim 1$ where $n \sim 10^4 n_4$ cm^{-3} at a temperature $T_2 < 1$ where $T = 10^2\ T_2$ K (ref. 7). X rays with energies $\varepsilon \gtrsim 2$ keV pass through such a cloud with little attenuation since it is only a few parsecs in size. The accretion radius

$$R_{\mathrm{A}} \simeq \frac{10^{16}}{(T_2+v^2)}\ \mathrm{cm}$$

yields luminosities $L \sim 10^{39}\, n_4(T_2+v^2)^{-3/2}$ erg s^{-1} in the case of a neutron star, and $L \sim 5\times 10^{37}\, n_4(T_2+v^2)^{-3/2}$ erg s^{-1} in the case of a $1 M_\odot$ white dwarf. The short-wavelength radiation, $\varepsilon > 13.6$ eV from such luminous sources would heat the accretion flow above 10^4 K, resulting in instabilities on a free-fall timescale, $t_{\mathrm{ff}} \sim 10^{11}\ R_{16}{}^{3/2}$ s, where R_{16} is the choking radius in units of 10^{16} cm.

Short timescales occur if the compact object has a substantial velocity, $v \gtrsim 100$ km s^{-1}. Many lone neutron stars may perhaps be expected to travel at such velocities, and I now concentrate on this possibility. An accretion radius $R_{\mathrm{A}} \simeq 10^{11}\ v_{300}{}^{-2}$ cm yields a luminosity $L \sim 3\times 10^{31}\, n_4\, v_{300}{}^{-3}$ erg s^{-1} and $t_{\mathrm{ff}} \sim 3\times 10^3\ R_{11}{}^{3/2}$ s. The precise form of the X-ray spectrum is unknown, but the blackbody temperature of low-luminosity neutron stars is $\sim 10^5$–10^6 K, and thus much of the radiation may emerge at energies $\varepsilon < 1$ keV. The absorption of a number, N_{ph}, of soft X rays ionises the surrounding region out to a radius R_{i} such that $N_{\mathrm{ph}} \simeq \frac{4}{3}\pi R_{\mathrm{i}}{}^3\, n$, provided that the optical depth through R_{i}, $n\sigma R_{\mathrm{i}}$, exceeds unity. The optical depth criterion demands that $R_{\mathrm{i}} \gtrsim 2\times 10^{13}\ n_4{}^{-1}$ cm, given [8] the photoelectric absorption cross section, σ. This in turn requires $N_{\mathrm{ph}} \gtrsim 4\times 10^{44}\ n_4{}^{-2}$, which is adequately supplied by $\sim 10^{35}$ erg of ~ 50 eV photons. The upper limit on the timescale over which the photons can be supplied is a crossing time of R_{i}, $t_{\mathrm{cr}} \sim 10^6$–$10^7$ s, the recombination timescale being much larger, $t_{\mathrm{r}} \sim 10^9\ n_4{}^{-1}$ s. An ionised region can therefore form if a few per cent or more of the neutron star luminosity emerges in the 13.6–50-eV band, assuming $v_{300} \sim 1$.

The absorbed energy not only goes into ionisation and dissociation of hydrogen molecules and atoms, but also into heating. The resultant temperature, $T \sim 10^4$–10^5 K will cause a large pressure difference to exist between the ionised region and the surrounding molecular cloud. R_{i} thus expands supersonically at $v_{\mathrm{s}} \sim 30$ km s^{-1} into the cool exterior, shock heating and dissociating the hydrogen molecules. The expansion is not adiabatic due to the loss of energy in dissociation. The temperature drops by a factor of ~ 10 to $\sim 3{,}000$ K in this process[9], resulting in an overall 40-fold increase in density behind the shock. The material then cools to ~ 100 K in $\sim 10^5$ s provided that the ionised fraction in the cooling gas exceeds 10% (ref. 10). The overall density enhancement in what is then essentially an isothermal shock may thus amount to a factor of $\sim 10^3$, residing in a shell of thickness $d \sim 10^{-3}\Delta R_{\mathrm{i}}$, where ΔR_{i} is the amount by which R_{i} has increased. The ionised zone approximately resembles a stand-off cone lying with its axis along the direction of motion of the neutron star.

Assume that a transient increase in luminosity, perhaps due to a density enhancement, causes a larger, roughly spherical, ionised region to form. Significant deceleration of R_{i} will only occur when an equal mass has been swept up in the shell, that is $\Delta R_{\mathrm{i}}/R_{\mathrm{i}} \sim 0.3$. When the compact object reaches the shell, $\Delta R_{\mathrm{i}}/R_{\mathrm{i}} \sim v_{\mathrm{s}}/v_{300} \sim 0.1$, and thus $d \sim 10^{-4}\ R_{\mathrm{i}}$. The density enhancement in the shell causes L to rise to $\sim 3\times 10^{34}\, v_{300}{}^{-3}$ erg s^{-1} on t_{ff}, subsequently dropping on a similar timescale after d has been crossed. The total burst energy is $\sim 10^{38}$–10^{39} erg, only a few per cent of which need be in photons creating a further ionised region beyond the shell. The X-ray bursts then repeat on intervals of $t_{\mathrm{cr}} \sim 10^7$ s. The relatively short cooling time of the dense shell prevents it from being evaporated by the low steady X-ray flux.

The observed bursts, which may have come from NGC5367, were separated by ~ 200 d and each lasted for several hours[5]. The observed 2–10-keV luminosity was $\sim 10^{34}$ erg s^{-1} during each burst. The above discussion suggests that a lone, fast moving, neutron star may be responsible. The probability that such a neutron star intersects a globule of volume ~ 10 pc^3 may be as high as 0.03, if there are as many as 10^9 suitable neutron stars within a scale height of ~ 500 pc about the galactic disk. The discussion is perhaps more relevant in indicating the possibilities for detecting burst like phenomena from molecular clouds optically thin to X rays within the plane of the Galaxy. The high galactic latitude ($b \sim 20°$) of the NGC 5367 events probably aided in their detection. Slower moving neutron stars, $v \sim 50$ km s^{-1}, may lead to events of longer duration and higher luminosities, possibly resembling Aquila X-1 and 3U1630−47 (refs 11, 12). White dwarfs may also give rise to weaker burst phenomena, as approximately half the accretion luminosity emerges in the ultraviolet[13], thereby increasing their potential to create ionised zones.

A slow moving neutron star, $v \sim 10$ km s^{-1}, moving through a region of density $n \sim 10^8$ cm^{-3} can give rise to very high luminosities, $L \gtrsim 10^{38}$ erg s^{-1}. Compton heating of the accreting gas, as well as radiation pressure effects, may choke the flow at relatively small radii, $R_{\mathrm{c}} \sim 10^{11}$ cm $\ll R_{\mathrm{A}}$ (ref. 4). Accretion may still proceed beyond R_{c}, and a dense, convectively unstable shell may result. Luminous X-ray bursts repeating on a timescale $t_{\mathrm{cr}} \sim 10^4$–$10^5$ s, caused by the passage of the neutron star through the dense shell enveloping the hot bubble produced from the previous burst, can occur if $t_{\mathrm{cr}} < t_{\mathrm{s}}$, the timescale on which the shell dissipates. The actual choking process is, as discussed in ref. 4, likely to be very complex and no detailed estimate is attempted here. Magnetospheric effects, for example, can modify the structure of the burst. Nevertheless, such bursts may in principle occur, and a suitably dense region may occur in the outer envelope, $R \sim 10^{14}$ cm of a red giant star undergoing mass loss. An accretion disk may form if the accreting material has sufficient angular momentum, as might be the case if the neutron star orbits the giant. The presence of a disk would stop bursts from occurring, but, as it depends on $R_{\mathrm{A}}{}^4$, however, a disk need not occur. Bursts such as those observed from NGC6624 (3U1820−30) (ref. 14) may be related to this process. Optical photographs[15,16] of globular cluster cores indicate the presence of luminous red giants.

I thank M. Begelman, J. E. Pringle and M. J. Rees for discussions.

Continuous increase of Hubble modulus behind clusters of galaxies

VARIOUS authors have suggested the existence of real fluctuations to Hubble's law (proportionality of redshift to distance) as a function of the position of sources on the sky map. Karoji and Nottale[1] have examined the possibility of a variation of the Hubble constant H associated with the passage of incoming light through rich clusters of galaxies. We confirm here their positive answer by a more detailed and precise statistical analysis. We show that there is an effective continuous effect depending on the relative distance of the line of sight of any given source to the centre of the intervening clusters. We thus conclude that we are dealing with a real physical effect, tied to the presence of these clusters.

It has been shown[1] that the Hubble modulus

$$h_{\mathrm{m}} = \log V - 0.2\, m = \log H - 0.2\, M - 5$$

where V is radial velocity, H the Hubble constant, m and M, apparent and absolute magnitude of a galaxy, is significantly higher for galaxies located within and behind rich clusters of galaxies (denoted region B) than for intercluster objects (denoted region A). This result has been suggested on four independent samples[1–4] and confirmed by analysis of brightest cluster galaxies[5]. The method used previously—comparison of the mean values $\langle h_{\mathrm{m}} \rangle_{\mathrm{B}}$ against $\langle h_{\mathrm{m}} \rangle_{\mathrm{A}}$ through an application of Student's t test, was a rather crude one. We present here a new method of analysis of h_{m} variations as a function of a continuous variable. Of course, if each independent sample had been rich enough, it would have been advisable to construct h_{m} 'isovalues' on the sky map. Since this is not the case, we have devised an alternative method.

First, rich clusters of galaxies being defined as in ref. 1, we classify galaxies as:
(1) Cluster galaxies, if they are situated within the limits (as defined by Zwicky *et al.* in CGCG[6]) of a cluster, and if their radial velocities V are within an interval of 6 σ around the mean cluster velocity (the mean value of σ for the clusters used in this analysis is around 750 km s^{-1}), that is

$$V_{\mathrm{cl}} - 3\sigma(V) \leqslant V \leqslant V_{\mathrm{cl}} + 3\sigma(V)$$

(2) Galaxies more distant than a cluster if $V > V_{\mathrm{cl}}$ outside Zwicky's limits or $V > V_{\mathrm{cl}} + 3\sigma(V)$ inside them.

Second, we refer each galaxy to a subsample of clusters nearer than it, or to which it belongs, and calculate the ratios θ/R, where θ represents its angular distance to a cluster centre, and R the angular cluster radius. Then we define a parameter α as the minimum of θ/R values, that is, $\alpha = \min \theta/R$. Centres and radii of clusters are taken from ref. 6.

Finally, h_{m} values are plotted with respect to α for a given sample of galaxies.

We present here the results obtained on the sample of Markarian galaxies identified in ref. 6, described and listed in ref. 4 (apparent magnitudes taken from ref. 6). This sample is of course magnitude limited ($m \leqslant 15.7$), which implies the presence of a Malmquist bias (distant galaxies are brighter in the mean than nearer ones) so that the h_{m} values increase with radial velocity. So we have built an unbiased subsample by taking only the brightest Markarian galaxies, $h_{\mathrm{m}} > 0.96$. The clusters of galaxies used here are listed in ref. 3.

Figure 1 is a plot of h_{m} against α (for $\alpha \leqslant 6$). There is clearly a continuous decrease of h_{m} for $0 \leqslant \alpha \lesssim 3$. A quantitative analysis gives highly significant results.

First we have studied the distribution of h_{m} values subdivided with respect to α into bins of 10 points each (Table 1). If cluster galaxies (4 points) are excluded, the first bin yields $\langle h_{\mathrm{m}} \rangle = 1.170 \pm 0.031$ ($0.4 \leqslant \alpha \leqslant 1.7$) instead of 1.144 ± 0.029. These values might be compared with h_{m} for $\alpha \gg 1$, which are of the order of 1.05 ± 0.02 (Table 1).

A second method is to find the regression curve corresponding to h_{m} against α values. It is clear from Fig. 1 that a single line cannot account for the whole distribution. There is a strong decrease up to $\alpha \simeq 3$, and for $\alpha > 3$, the distribution is practically flat. Indeed, the equation of the least-square line for $\alpha \leqslant 3.3$ (cluster galaxies excluded) is $h_{\mathrm{m}} = 1.217 - (0.0567 \pm 0.016)\, \alpha$, the correlation coefficient being 0.48, which means that the probability that no correlation exists between h_{m} and α is only 0.001. The results of the least-square linear fit for $\alpha \leqslant 3$ $\alpha > 3$ are

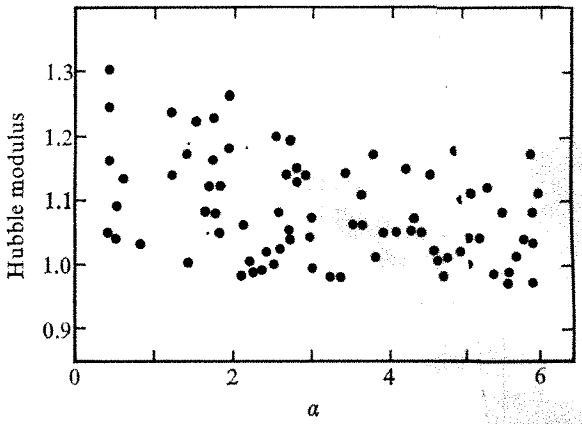

Fig. 1 Hubble modulus against normalised projected distance to nearer cluster $\alpha = \theta/R$ for unbiased sample of Markarian galaxies ($h_{\mathrm{m}} > 0.96$).

$$\alpha \leqslant 3,\ n = 38,\ h_{\mathrm{m}} = 1.207 - (0.0502 \pm 0.0183)\, \alpha,\ \rho = 0.41$$

$$\alpha > 3,\ n = 43,\ h_{\mathrm{m}} = 1.080 - (0.0048 \pm 0.0109)\, \alpha,\ \rho = 0.07$$

There is practically no correlation when $\alpha > 3$. We think that a good fit of the distribution of Fig. 1 for galaxies behind clusters is then achieved with

$$h_{\mathrm{m}} = 1.21 - (0.055 \pm 0.018)\, \alpha \text{ for } \alpha \lesssim 3, \text{ and } h_{\mathrm{m}} = 1.05 \text{ for } \alpha > 3$$

As the preceding method gives the statistical significance of only part of the distribution we have also tried to give a numerical account of it by a unique curve: Fig. 1 suggests a law of the shape $\exp(-a\alpha^2)$. We find the following best fit: $h_{\mathrm{m}} = 1.051 + (0.099 \pm 0.025) \exp(-0.17\, \alpha^2)$, significant at the 4 σ level (Fig. 2).

Finally, these results are confirmed by the analysis of the effect through the method of Karoji and Nottale[1]. The mean value of h_{m} in region B (that is, $\alpha \leqslant 2$) is 1.141 ± 0.018 ($\pm$ s.e.m.), in region B* ($\alpha \leqslant 2$, cluster galaxies excluded) 1.153 ± 0.010 and in region A, 1.057 ± 0.008. Then the differences are respectively 0.084 ± 0.017 and 0.096 ± 0.018, significant at the 4.9 σ and 5.3σ levels.

It is not the purpose of this letter to discuss possible observational explanations of this effect. This has been started in the original paper of Karoji and Nottale[1] and in refs 3 and 4. A complete analysis is now in preparation. We will only discuss two particular points.

It is possible that our method of classifying galaxies with respect to clusters has an influence on the effect. Indeed a bias

Table 1 Analysis of data from Fig. 1

(1)	α (2)	$\langle h_{\mathrm{m}} \rangle$ (3)
1—10	0.4—1.2	1.144±0.029
11—20	1.4—1.8	1.123±0.023
21—30	1.9—2.5	1.068±0.033
31—40	2.6—3.0	1.101±0.018
41—50	3.0—3.8	1.056±0.022
51—60	3.9—4.7	1.061±0.016
61—70	4.7—5.4	1.057±0.021
71—80	5.5—6.0	1.045±0.021
81—85	6.1—6.8	1.056±0.046

Data from Fig. 1 was analysed into bins of 10 points each. (1), Ranks of points in a bin; (2) α interval; (3), mean h_{m} in each bin $\pm$ s.e.m. $\sigma/\sqrt{n}$.

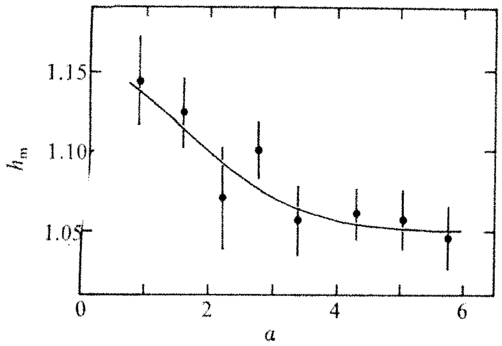

Fig. 2 Mean values of h_m against α in bins with errors bars and regression curve (see Table 1 and text). The last bin, containing only five points, is excluded.

could be present if clusters are actually greater than given by CGCG limits. So we have used another distance criterium, that is, galaxies are more distant than a cluster if $V > V_{cl} - 3\sigma(V)$. This change introduces no difference in our results, since only four galaxies are concerned by it, three slightly, and one ($h_n = 1.04$) having $\alpha = 5.1$ changed in $\alpha = 2.2$.

The second point is the possible relation with the Rubin *et al.* effect[7,8] which is now interpreted by them as a motion of the local group with respect to ScI galaxies ($3{,}500 < V < 6{,}500$). The simplest way to take it into account is to correct our data for this motion ($V_{GL} = 450$ km s^{-1} towards $\alpha = 4$ h 12 min, $\delta = 36°$). Our results are practically not affected by this correction. We obtain $\langle h_m \rangle_B{}^* - \langle h_m \rangle_A = 0.090 \pm 0.018$ ($t = 5.0$) and $\langle h_m \rangle_B - \langle h_m \rangle_A = 0.076 \pm 0.017$ ($t = 4.5$). It thus seems clear that if this solar motion exists, it is a small effect and independent of the Karoji–Nottale effect at the distances involved with our sample of Markarian galaxies ($V \sim 10{,}000$ km s^{-1}).

Remembering that this analysis was performed on a subsample not affected by a Malmquist bias, our conclusion is that these results strongly support the existence of a dependence of redshift on the position of galaxies relative to concentration of matter, that is, clusters of galaxies.

Polysaccharides and infrared spectra of galactic sources

Observations over the infrared waveband 2–30 μm available for a number of astronomical objects are shown here to be reconcilable with the transmittance properties of polysaccharides. Using an experimentally determined transmittance spectrum for cellulose we can readily relate astronomical data in the 2–4-μm, 8–13-μm and 15–30-μm wavebands and we obtain close fits to astronomical spectra in these several bands. From this detailed spectral agreement we consider it reasonable to infer the detection of interstellar polysaccharides. The identification of this highly complex macromolecule, presumably formed by an abiogenic processing of interstellar formaldehyde, could have a profound bearing on interstellar chemistry including the evolution of prebiotic molecules.

Physical conditions within dense molecular clouds are known to favour the production of organic molecules, probably through electron-exchange reaction chains initiated by the cosmic-ray ionisation of hydrogen and helium atoms[1,2]. The majority of such molecules are fragile, however and are easily broken up by exposure to an appreciable intensity of starlight, which they will be if the parent clouds become dispersed to the normal density of the interstellar gas. Thus, since the interstellar gas undergoes alternating phases of compression and evaporation, there must be corresponding alternations of chemical complexity—molecular dissociations taking place during evaporation and association during compression. As Sagan has pointed out[3] such alternations provide a selective process for the emergence of those chemical forms that can best withstand the adverse conditions of the evaporative phases.

With the exception of H_2, H_2O and CO the most ubiquitous and very likely the most abundant molecule in the interstellar medium is H_2CO, probably formed by electron-exchange reactions[1,2]. Formaldehyde would seem an obvious example of a fragile molecule forming within dense clouds which dissociates as soon as the clouds evaporate. This will certainly be the case for individual molecules, but formaldehyde has the remarkable property of polymerising in many ways, the polymers being far more resistant to break-up than the individual molecules.

The most refractory polymers are probably the polysaccharides, which have substructures built from H_2CO units, substructures with the empirical formula $(H_2CO)_n$, where $n \geqslant 3$. The commonest polysaccharides, cellulose and starch with $n = 6$, are particularly stable because each $(H_2CO)_6$ is able to form itself into a very stable ring, with the polysaccharide then becoming a chain of hexagonal ring substructures. Cellulose can maintain its structure (in a vacuum or in an inert atmosphere of low density) probably up to a temperature of around 625–900 K. (Laboratory data for wood cellulose indicate stability up to about 620 K (ref. 4), but in low-pressure interstellar conditions and in the absence of free oxygen there could exist polysaccharides similar to cellulose which can withstand temperatures up to about 900 K.)

In accordance with the selection occasioned by the alternating phases of compression and evaporation of the interstellar gas, can we expect fragile molecules of interstellar formaldehyde to have evolved into stable polysaccharides like cellulose and starch? Without supporting evidence, this would seem a bold conclusion, to say the least. Yet with the evidence presented here an affirmative answer does indeed seem warranted.

Interstellar solid material is strongly absorbing in two infrared bands, centred at 3 μm and at 10 μm. Because crystals of water-ice absorb at about 3 μm and magnesium silicate at 10 μm, it has seemed natural to attribute the infrared properties of interstellar 'dust' to a mixture of water-ice particles[5] and magnesium-silicate grains[6,7]. Indeed both these assignments are likely to be appropriate in certain types of localised region. But the detailed correspondence of a silicate–ice model to the observed infrared spectra of a wide range of galactic sources is not good, especially if one takes account of experimentally measured absorption spectra for silicate particles[8]. The failure to obtain detailed correspondences is the more disturbing because ice and silicate grains are rather simple materials, without much scope for their properties to be changed by other substances. For such simple materials the issue should be clear-cut, yet it is not. Rather it is frequently necessary to appeal to uncertainties in the astronomical models to explain away discrepancies between observation and theory.

This was the background which made it seem worthwhile to consider whether the infrared properties of interstellar 'dust'

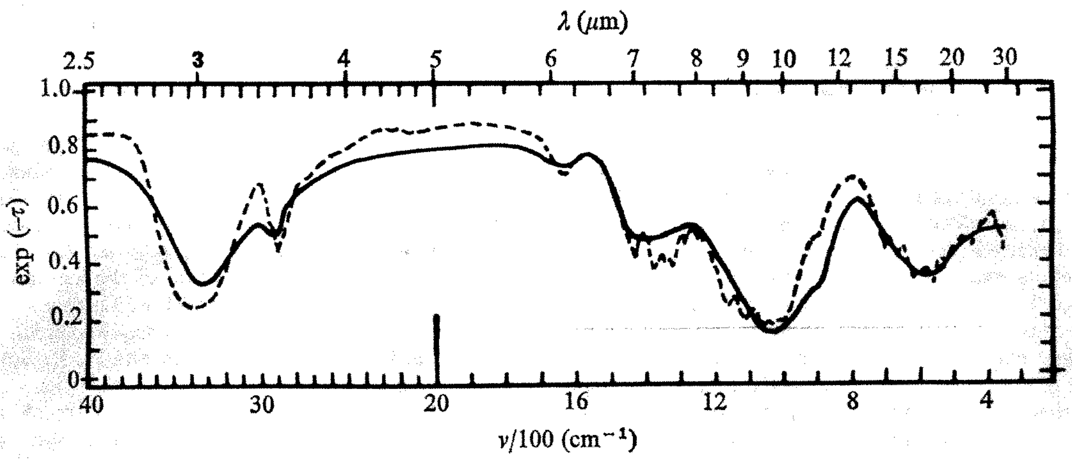

Fig. 1 Dashed curve is the transmittance data for cotton cellulose ('A cellulose 1') from ref. 9. Solid curve represents a smoother spectrum which we have estimated for an ensemble of related polysaccharides.

could be attributed to polysaccharides. Of all the polysaccharides, cellulose seems, because of its economic importance, to have been the most extensively studied, and the broken curve of Fig. 1 is reproduced from a calibrated study of the infrared spectra of cotton and its modifications[9]. Cellulose is immediately seen to have broad absorptions both at 3 μm and 10 μm, with the latter quite devoid of any unwanted spike of high transmittance, such as has been reported for silicates[8]. Transmittance values, $e^{-\tau}$, where τ is the opacity of the experimental sample, can be read off from the curve. Other polysaccharides possess similar transmittance properties, with slight wavelength displacements for the same general features (see ref. 12). The effect of such displacements for an ensemble of polysaccharides would therefore leave the general features unchanged, but must produce smoothing, as we have indicated by the solid curve of Fig. 1.

If the interstellar 'dust' has transmittance values corresponding to cotton cellulose, then the emission per unit wavelength band from an optically thin cloud of 'dust' at temperature T will be proportional to $\tau\ B_\lambda\ (T)$, where B_λ is the Planck function (This assumes the validity of the Rayleigh approximation for small particles with non-resonant absorptions. Technical issues relating to this assumption will be discussed elsewhere). Choosing the constant of proportionality to give a normalisation of 2.00 at $\lambda = 10$ μm, and taking $T = 175$ K, we obtain the dashed curve shown in Fig. 2. The solid curve is calculated from the estimated smoother spectrum for a polysaccharide ensemble (solid line in Fig. 1). Since these calculated curves give excellent fits to the observations for the Trapezium Nebula[10,11] (which are also given in Fig. 2) we consider that a *prima facie* case for the existence of interstellar polysaccharides has been established.

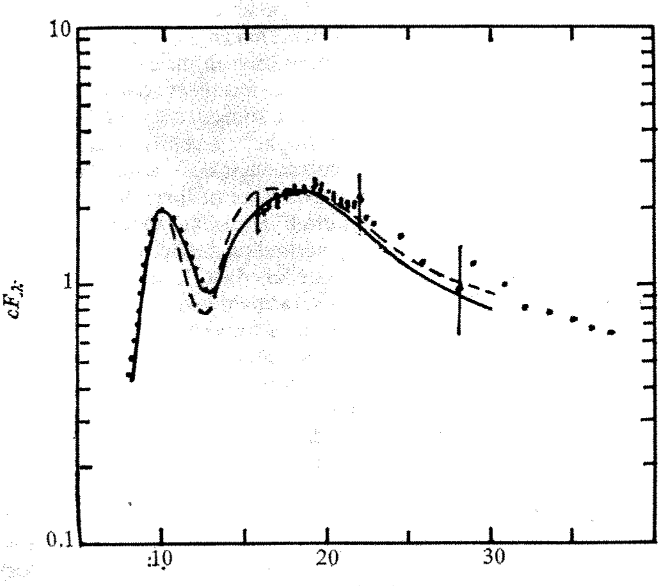

Fig. 2 Normalised flux from the Trapezium Nebula (refs 11, 12) (points) compared with emission from polysaccharide grains of temperature 175 K. Dashed curve is for cellulose (compare Fig. 1); solid curve corresponds to the polysaccharide ensemble spectrum as in Fig. 1.

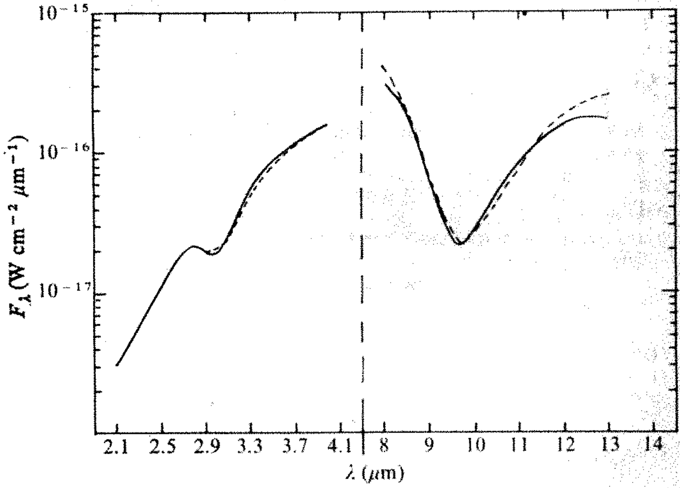

Fig. 3 Solid curve is a plot of the normalised flux against wavelength for an optically thin polysaccharide model with $T = 43$ K, $\alpha = 2.6$. Dashed curve is the observational data for the astronomical source H_2O 610+18.

It has become well known among astronomers that material with the same emissivity as that which gives rise to the Trapezium spectrum also provides a thoroughly satisfactory explanation of the observed characteristics longwards of 8 μm for a wide range of other sources (see refs 13, 14). Hence the agreement of the cellulose data (and of the smooth curve of Fig. 1 in particular) with the Trapezium Nebula already ensures that the polysaccharide data must fit the observed characteristics longwards of 8 μm for the same wide range of sources. Our concern here will therefore be directed to the shorter-wave band 2–4 μm, since it is here that a more interesting situation arises.

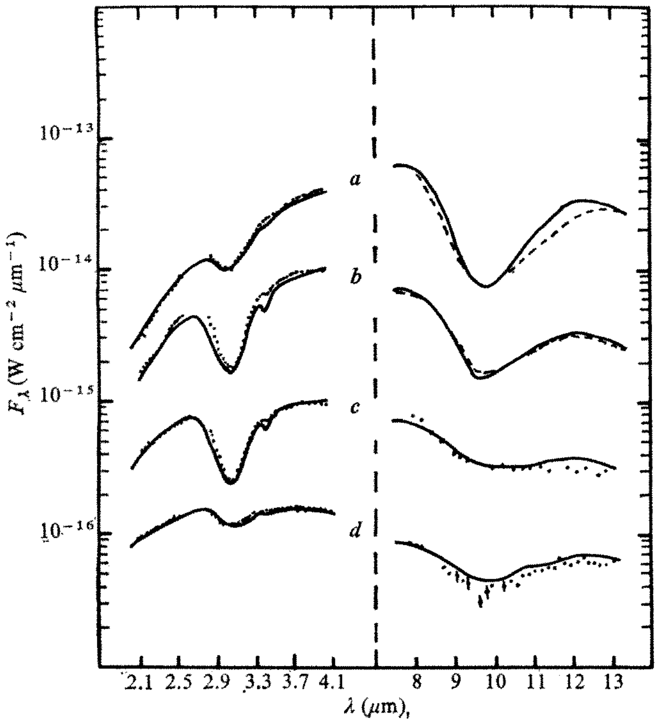
We ask two questions. First, is there a satisfactory agreement of the polysaccharide data to observation for the shorter wavelength band, 2–4 μm? And second, can the shorter wavelength band be related in its intensity to the intensity of the longer wave band?

Taking the latter question first, Fig. 3 shows the relation of observations (broken curve) for the source H_2O 610+18 to the calculated curve (solid) given by the following model:

An optically-thin emitting cloud of temperature T lies behind a foreground cloud that is cool enough for its emission to be not relevant over the wavelength range under consideration here. The relative intensity is determined in the same way as for the Trapezium Nebula, except that an extra factor $\exp(-\alpha\tau)$ must be included to take account of absorption by the cool cloud. Thus the intensity is determined by $\tau B_\lambda(T)\exp(-\alpha\tau)$. The particular values chosen to represent the source H_2O 610+18 were $T = 430$ K, $\alpha = 2.6$. The answer to the first of the above questions is therefore affirmative, since the two wavebands are properly related (see also ref. 15, which gives a similar calculation for the source OH 26.5+0.6 taken over the very wide wavelength range of 2–30 μm).

The answer to the second question is also affirmative, as can be seen from the excellent fit of observation and calculation for the four sources given in Fig. 4. The model used here for the 2–4-μm waveband was the same as that described above, except that the hot emitting cloud was taken to be optically-thick. This has the effect of simplifying the formula used in the calculation, through the omission of the factor τ, to $B_\lambda(T)\exp(-\alpha\tau)$. The values chosen for T and α are shown in the legend to Fig. 4. The details of these calculations, together with a discussion of several other sources, will be given elsewhere. In particular, the matching of the shorter and longer wavebands for these sources which involves a new feature in the model, will be discussed separately.

Fig. 4 Cases *a–d* represent observational data (points) and normalised theoretical fluxes (solid curves). *a*, Observational points for CRL2591 × 20; theoretical curve on short wave side corresponds to an optically thick polysaccharide model with $T = 650$ K, $\alpha = 0.6$. *b*, Observational points for BN × 4; theoretical curve on short wave side is for an optically thick model with $T = 650$ K, $\alpha = 1.75$. *c*, Observational points for NGC2264IR; theoretical curve on short wave side is for optically thick model with $T = 800$ K, $\alpha = 1.7$. *d*, Observational points for CRL490 ÷ 3; theoretical curve on short wave side is for optically thick model with $T = 850$ K, $\alpha = 0.25$. All the observational data are from ref. 12 and the theoretical curves are normalised to match the observations at one wavelength. The longwave calculations involve model refinements to be discussed elsewhere.



We conclude by noting that near 3 μm the sources of Fig. 4 show dips of very different depths one to another. Yet the same transmittance data was used in all cases—the difference arises from the choices of T and α. In the past, the dips at 3 μm have been attributed to water–ice, with *ad hoc* assumptions of different degrees of condensation of the ice necessary in order to explain the variability of the dips. There are no such *ad hoc* assumptions here. Nor is water–ice required at all.

We thank Drs A. M. Olavesen and N. R. Smith for useful information.

Mechanism for formaldehyde polymer formation in interstellar space

CONSIDERING the properties of galactic dust clouds in the wavelength region 8–12 μm Wickramasinghe[1] concluded that formaldehyde undergoes polymerisation in interstellar space to polyformaldehyde. Applying more stringent constraints for matching infrared spectra of galactic sources over the waveband 2.5–30 μm Hoyle and Wickramasinghe[2,3] recently argued for the identification of interstellar polysaccharides—which could be regarded as a further chemical evolution of formaldehyde polymers. A considerable fraction of all interstellar O and C may be locked up as some form of polymerised formaldehyde, making up the main component of interstellar dust. I argue here that molecular tunnelling in condensed formaldehyde is the only viable mechanism for the formation of formaldehyde polymers in interstellar conditions. Such a polymerisation process may be initiated by the action of ionising radiation.

The concentration of gaseous formaldehyde in dense molecular clouds with density $n_{\mathrm{H,H_2}} \sim 10^4$ cm^{-3} is $n_{\mathrm{H_2CO}} \sim 10^{-5}$–$10^{-6}$ cm^{-3}. Using appropriate values for the heat of polymerisation of gaseous formaldehyde with the formation of crystalline polyoxymethylene (POM) ($\Delta H = 16{,}700$ cal mol^{-1} at 1 atm) and of the corresponding decrease in the entropy ($\Delta S = 42.6$ cal mol^{-1} deg^{-1}) (ref. 4) one can easily see that at the above-mentioned $n_{\mathrm{H_2CO}}$ values interstellar POM would be thermodynamically stable below ~ 100 K. Furthermore, silicate grains of dimension $\lesssim 0.1$ μm (ejected from cool stars) which many serve as the sites of condensation and polymerisation of formaldehyde have temperatures below ~ 20 K. Thus thermodynamical considerations confirm the possibility of the formation of stable polyformaldehyde (and related polymers) in cold regions of interstellar space. In such circumstances the kinetics of polymerisation must have a decisive role.

Although direct polymerisation on the surfaces of interstellar mineral grains can be initiated by ionising radiation, the rate of propagation of polymer chains at very low temperatures could be vanishingly small[5]. Indeed, an Arrhenius-type extrapolation of our data[6–10] on the kinetics of formaldehyde polymerisation at temperatures $\sim$ 77–140 K to lower temperatures leads to the conclusion that the time for the addition of each new link to the growing polymer chain (with the activation energy $E \sim 2{,}000$–$2{,}500$ cal mol^{-1}) would be $\tau_E \sim 10^4$ yr at 20 K, $\tau_E \sim 10^{30}$ yr at 10 K and $\tau_E \sim 10^{100}$ yr at 4 K. Nevertheless, the length of the chains (υ) of formaldehyde polymerisation which is close to the radiation-chemical yield of this process $G = g\upsilon$) (g is the number of primary active centres of polymerisation produced by 100 eV of absorbed X or γ radiation; $g \sim 1$) is quite large and reaches $\upsilon \sim 10^7$ at 140 K, $\upsilon \sim 10^5$ at 77 K and $\upsilon \sim 10^3$ at 4 K (refs 6–10). At first sight the value of $\tau_E \sim 10^4$ yr would seem compatible with the possibility of an Arrhenius-type, over-barrier growth of sufficiently long POM chains in interstellar grains, because the lifetime of dust clouds limited by their gravitational collapse or by clould–cloud collisions is typically $\sim 10^5$–10^7 yr (refs 2,3,11). As will be shown below, however, an insurmountable obstacle for the over-barrier growth of polymer chains is the saturation of the radiation-chemical formation of chain propagating active centres—radicals or ions.

The steady-state concentration of radicals R_s achieved in conditions of external irradiation of molecular solids, even at very low temperatures ($\lesssim$ 4 K), corresponds to rather small saturation values: $R_s \sim 10^{-3}$–10^{-2} and does not depend on the intensity of radiation. In principle there can be two conceivable causes of such saturation:

(1) Radicals and other active centres can be formed in solids only in the vicinity of various traps of energy—for example, defects and impurities. In such a case active centres formed by radiation can remain for a very long time (practically an infinite time) localised at some imperfections. Thus R_s is simply the fraction of pre-existing imperfections in the solid and obviously does not depend on the intensity of external radiation as long as the formation of additional defects by radiation itself can be neglected.

(2) The disappearance of radicals formed by radiation is due to recombination, and moreover the rates of both formation and recombination of radicals are proportional to the intensity of radiation[13]. In such circumstances R_s would again be independent of radiation intensity.

In this latter case[2] active centres are spatially delocalised and therefore R_s is equal to the part of the time (x_{act}) spent by each molecule in an active state. As shown by numerous experiments (see, for example, ref. 11) it is precisely this mechanism which causes the saturation of the yield of radicals at 77 K. Investigations[13] of the formation and disappearance of radical pairs at much lower temperatures (down to 1.5 K) have demonstrated that the migration of radicals proceeds at least down to 35 K and most probably even to lower temperatures. Therefore R_s characterises the value of $x_{act} \sim 10^{-3}$–10^{-2} rather than the degree of imperfection of the solid. (Migration of free radicals as such is not required for the correctness of the treatment of R_s values as a measure of the time-probability rather than space-probability of finding an active centre at any site in the solid. The equality $R_s = x_{act}$ which is the premise of following estimates can be fulfilled for any other mechanism of free valency migration—for example in cases of tunnelling of H-atoms and/or electrons which is certainly feasible even at very low temperature.)

Assuming that active centres are produced by ultraviolet radiation[10] and that the density of quanta $\rho_{UV} \sim 10^{-2}$ cm^{-3}, that is their flux $j_{UV} = \rho_{UV}c \sim 3 \times 10^8$ cm^{-2} s^{-1}, we obtain the rate of absorption of ultraviolet quanta by interstellar dust molecules as 3×10^{-10} s^{-1}, so that the characteristic time between two successive ultraviolet absorptions by a molecule is $\tau_{UV} \sim 100$ yr. Meanwhile the fraction of time spent by any monomer molecule in its active state when it is able to participate in chain propagation is only $\tau_{act} = x_{act}\ \tau_{UV} \sim 0.1$–$1$ yr. When $\tau_E > \tau_{act}$, the probability of formation of a polymer chain of υ links is

$$w_v = [\tau_{act}(\tau_{act} + \tau_E)^{-1}]^{v-1}$$

This expression decreases very fast with the increasing υ and therefore for the above-mentioned value of τ_E (20 K) $\sim 10^4$ yr, given by an Arrhenius-type extrapolation, the formation of even trimers is extremely improbable.

The validity of an Arrhenius-type extrapolation of data for $T \geq 77$ K to lower temperatures is highly suspect, however. In the conditions of our experiments[5–9] when the dose rate of ^{60}Co γ radiation (which initiated polymerisation chains) was ~ 10 rad s^{-1}, the characteristic time for absorption of γ quanta was also close to $\tau \sim 100$ yr, and $\tau_{act} \sim 0.1$–1 yr. Even at temperatures as low as 4 K the length of polymerisation chains reached $\upsilon \sim 10^3$. This implies that the time for the addition of one new link to the growing polymer chain τ_0 had to be much shorter than 10^{-3} $\tau_{act} \sim 10^3$–10^4 s.

Indeed, our experiments[5–9] have shown that the above-mentioned extrapolation of the average time τ_0 for the addition of one new link to the growing polyformaldehyde chain, based on Arrhenius' law, is absolutely inadmissible below temperatures around 77 K. The increase of τ_0 with the decrease of temperature in this region sharply slows down, and reaches an asymptotic plateau value: $\tau_0 \sim 10^{-2}$ s, below ~ 10 K with no further increase at lower temperatures. Such a value of τ_0 is $\sim$ 5–6 orders of magnitude below the value of τ_0 necessary for the formation of chains with $\upsilon \sim 1{,}000$ at 4 K. This conclusion, based on direct laboratory data, has a very important bearing on the existence and formation of polymerised formaldehyde in interstellar space. A semi-quantitative explanation for the existence of a low-temperature limit to the rate of growth of chains in the polymerisation of formaldehyde was attained by using the concept of molecular tunnelling in exothermic chemical reactions[14–16]. As can be seen from all the above-mentioned considerations, there are now sufficient grounds to affirm that molecular tunnelling is the only mechanism which can provide the formation of long chains of polymerised formaldehyde in interstellar space.

It would seem most promising and worthwhile to analyse the possible role of molecular tunnelling in the general context of the evolution of prebiotic macromolecules and in the wider field of cosmic organic chemistry with reference to conditions of interstellar space, comets and the early Solar System as well as the primitive earth.

Dust clouds and frictional generation of glow discharges on Mars

A REMARKABLE characteristic of those samples of the martian soil which have so far been analysed is the absence of carbonaceous matter down to the parts per billion (10^9) level[1]. As well as a lack of endogenous organic material there is no sign of the component expected from infalling carbonaceous meteorites. The inorganic particles constituting the fine martian soil seem to be extremely 'clean'—far cleaner than terrestrial desert or Antarctic analogues. I suggest here that glow discharges generated by friction within dust clouds might explain this apparent absence of carbonaceous matter. In addition glow discharges might account for some reactions noted in the Viking biological experiments.

Fine siliceous material is frequently raised by Martian winds to produce dust clouds, sometimes in enormous quantities sufficient to shroud the entire planet[2]. In the present cold, dry conditions[1] it seems inescapable that frictional electrostatic charging will occur. On Earth we see natural examples of this triboelectric phenomenon in sandstorms and dusty volcanic eruptions[3]. Laboratory studies have confirmed that movement and dispersion of many types of finely-divided material result in the separation of charge and the generation of considerable electrostatic potentials[4]. It is not essential that the system be heterogeneous: homogeneous particles of different sizes can take up opposite polarities. The magnet experiments on the Viking landers have demonstrated a certain heterogeneity in the martian soil[1], however. Separation of the particulate components of a charged cloud can produce oppositely charged regions within it. At the pressures existing in the lower terrestrial atmosphere the potentials may be equilibrated by a spark discharge—the most dramatic example being volcanic lightning[5]. At reduced pressures, however, charge equalisation is facilitated by glow discharge[6]. Experiments[7] show this mechanism to be most effective in the pressure range 0.1–10 torr: at the surface of Mars there is a dry 95% carbon dioxide atmosphere at a pressure of 5–6 torr (7–8 mbar; ref. 1). Studies of the glow discharge resulting from the generation of frictional electricity at low pressures were begun in the eighteenth century[8], but frictional devices were soon supplanted by more reliable and côntrollable sources of high potential for the investigation of electrical discharges in gases. I therefore decided to check experimentally on the effect of agitating dry powders at reduced pressure.

A 5-l Pyrex flask was rotated manually about a hollow stub axle, two O-rings providing a vacuum seal. The speed of rotation controlled the magnitude and form of agitation of the dust from gentle sliding to a continuous cascade, an oscillatory motion proving especially effective. Evacuation was accomplished through the hollow axle by a conventional vacuum system incorporating gauges, a gas bleed, and a two-stage rotary pump. With air as the gaseous medium and fine sand (previously washed and oven dried) as the particulate material it was found that discharges visible in a darkened room were readily excited over a wide range of reduced pressures. At 0.1 torr a faint greenish–white glow extended for more than 5 cm above the agitated sand, being somewhat more intense adjacent to the rising wall of the rotating vessel. The system was then isolated from the pump and air allowed to enter as required through a needle valve. In the pressure range of particular interest (4–6 torr) the continuous glow contracted and brightened, and was accompanied by long, forked, ribbon discharges about 1 cm wide darting intermittently through the cascade of dispersed grains. Occasional intense spots of light on the surface of the moving sand gave a 'twinkling' appearance. At 10 torr ribbon discharges became narrower and brighter, but less frequent. This progression continued until at 50 torr only bright twinkling discharges remained.

It is recognised that the glow discharge is a very effective scavenger of even the most tenacious traces of organic matter from surfaces (particularly silicates) because cleaning with such a discharge is the conventional final stage in preparing an astronomical mirror for aluminising[9]. The mechanism is primarily that of ion bombardment, but reactive intermediates produced in the gas phase may also be important[10]. It is therefore suggested that the fine, near-surface martian soil will have been subjected to repeated dissemination by seasonal winds and, while within these clouds, the separated particles exposed many times to the cleaning action of glow discharges. It will be noted that this process could operate discontinuously throughout an extended period of time right up to the present. It also differs from irradiation by solar ultraviolet in that the latter could not penetrate beyond the surface of a cloud or the undisturbed soil: the two mechanisms may be complementary.

In addition to the cleaning action, it is relevant to consider the accumulated chemical effects which may be produced by glow discharges[7]. It has been shown that they promote dissociation of molecular gases such as carbon dioxide, and can act as effective generators of ultraviolet light, ions, free radicals, atomic oxygen and ozone[11,12]. The last two in particular could persist for varying lengths of time after the discharge, and diffuse to subsurface locations in the grains to exert powerful oxidising effects. Potential products include peroxide bonds, percarbonates (which evolve oxygen and carbon dioxide on gentle warming, and oxygen on addition of liquid water) and hydrogen peroxide addition compounds[11]. It is therefore suggested that the widespread reddish coloration of the martian surface[1], as well as the unexpected reactions observed in the Viking biology experiments[13], could in part be due either directly or indirectly to glow discharges. Living microorganisms (including spore-formers) do not long survive exposure to glow discharges and their products[12], so on this basis the fine, red, surficial martian dust would seem unfavourable for life-detection experiments. A better sampling scheme might be coring in the postulated permafrost terrain[2]. It is perhaps ironic that in different conditions (notably in the presence of water) glow discharges can promote the abiogenic synthesis of organic molecules[7].

Finally, although it is not expected that glow discharges on Mars would be detectable from orbit (much less from Earth), it would seem worthwhile to attempt radiofrequency and electrostatic field measurements on future landings.

Daytime ionosphere scintillation associated with geomagnetic storms

EQUATORIAL spread F, although a night-time phenomena, has been reported on a few occasions during the dawn period[1]. This is thought to be due to the remains of irregularities produced during the night. Earlier results have also shown that ionospheric scintillations and spread F have

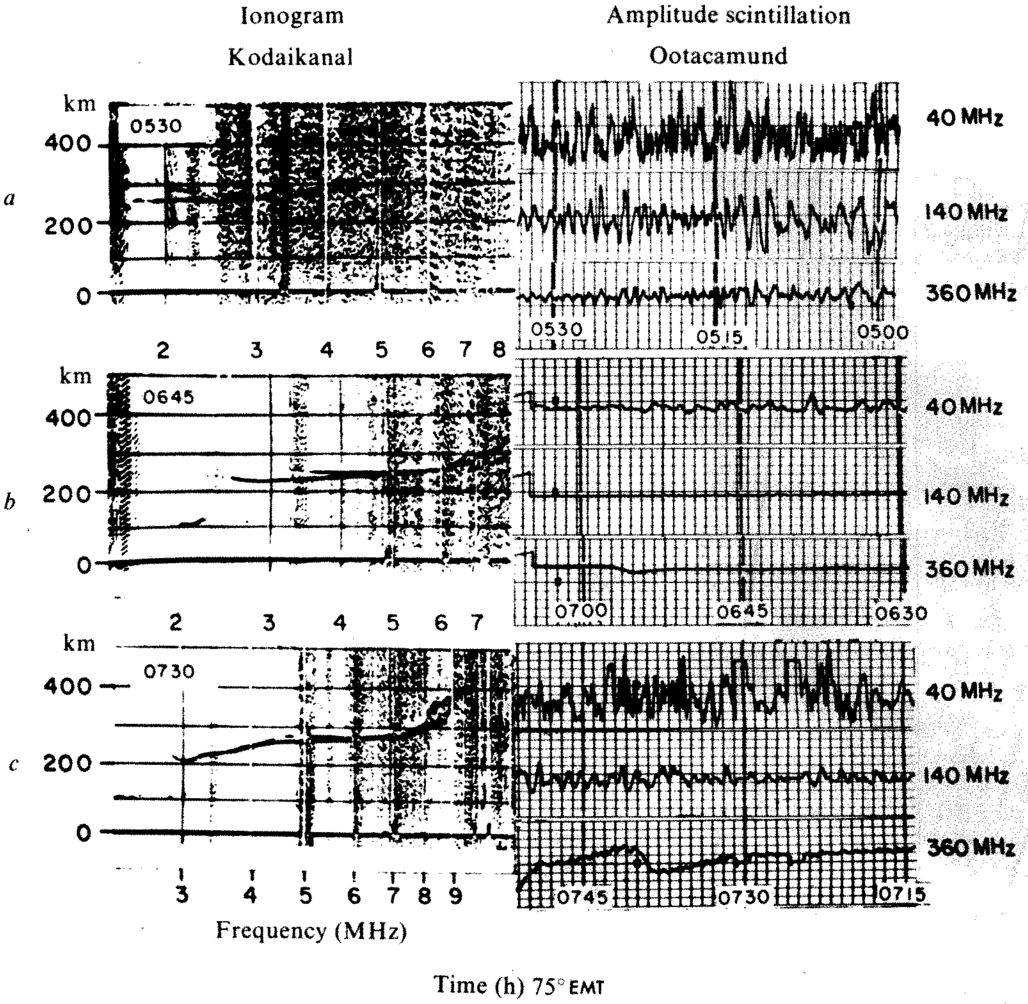

Fig. 1 Ionograms taken at Kodaikanal and the corresponding amplitude recordings of 40-, 140- and 360-MHz radio beacons at Ootacamund on 29 October 1975. Note the association between spread F and ionospheric scintillations specially during daytime (*c*).

a good correlation. These scintillations rarely occur between 0200 and 0800 LT, or around sunset hours[2]. The present article deals with a unique observation of the equatorial region, where the irregularities produced during the night have vanished, and started again after sunrise. The fresh irregularities caused spread F and ionospheric scintillations at 40, 140 and 360 MHz. These irregularities can be associated with a geomagnetic storm.

Figure 1 shows the sample records of the amplitudes of 40-, 140- and 360-MHz beacons as received at Ootacamund (11°4′N, 76°7′E) at 0530, 0645 and 0730 LT (75° EMT). To monitor the ionospheric condition we have compared these records with the corresponding ionograms taken at a neighbouring station Kodaikanal (10°2′N, 77°5′E). During the pre-dawn period on 29 October 1975, both the spread F and the scintillations were quite strong. This is shown by Fig. 1*a*; the scintillation index at 40 MHz was 97%. The spread F as well as the scintillations had disappeared after 0603 LT and one can see in Fig. 1*b* for 0645 LT, clear F traces and fairly smooth amplitude records. There were no more scintillation until about 0712 LT when there was sudden onset on all frequencies and these scintillations continued until 0848 LT. Figure 1*c* for 0730 LT shows spread F near the critical frequency together with scintillations on all the frequencies. No sporadic E irregularities were seen on the ionogram, thus, the scintillations were caused only by F region irregularities.

The Indian Institute of Geomagnetism, Bombay, had observed a gradual commencement type geomagnetic storm at 1800 LT on 28 October 1975. Although the planetary geomagnetic indices were not high on 29 October 1975, the equatorial D_{st} values showed an increase from 1400 UT (1900 LT) to 1800 UT (2300 LT) and a sudden drop afterwards reaching a minimum around 0800 UT (1300 LT). Thus the present observations seem to have occurred during the main phase of a strong geomagnetic storm.

The Faraday rotation angles were recorded at the same time as the amplitudes at Ootacamund. Using these data, total electron contents (TECs) at intervals of 5 min were computed. There were wave-like fluctuations in the TEC in the period of about 10 to 15 min.

Equatorial ionospheric scintillations in the early hours after sunrise is rare. Further, in the present case, the onset at 0712 LT was preceded by a no-scintillation period. Thus the scintillations around 0730 LT were not due to irregularities remaining from spread F of the previous night but were due to newly generated irregularities in the F region.

Various theories[3,4] have been proposed for the generation of spread F near the magnetic equator during the post sunset period. The example shown in Fig. 1*c* is an abnormal case and cannot be explained by normal features of the F region assumed in most theories. It is likely that the F region irregularities discussed here were associated with the geomagnetic storm prevailing during that period.

The authors are grateful to Professors K. R. Ramanathan, D. Lal, S. P. Pandya, R. G. Rastogi and K. Davies for their encouragement during the course of this work. We thank Professor R. G. Rastogi, for stimulating discussions, and Professor G. Swarup, for providing facilities for Radio Beacon Experiment at the Radio Astronomy Centre, Ootacamund. Volcanic dust veils and North Atlantic climatic change

One possible climatic control that has been neglected in empirical studies until recent years is the variation in the volcanic dust loading of the upper atmosphere. I shall discuss here the nature of the relationship between volcanic activity and the climate of the North Atlantic sector and its importance in relation to other proposed climatic controls on time scales up to 300 yr. Fluctuations on these time scales in a volcanic dust veil index (DVI) compiled by Lamb[1] and in parameters representative of the strength of the North Atlantic westerly winds and the temperature of central England are shown to be similar.

The DVI is an estimate of the amount of dust in the stratosphere injected by explosive volcanic eruptions. How the amount of dust input from an eruption is assessed depends on the type of observations available. The three methods generally used are based on the greatest depletion of the direct solar beam in middle latitudes, the estimated volume of solid matter dispersed as dust, and the lowering of the average air temperature in middle latitudes by the eruption. All available estimates are finally averaged (Lamb[1] gives further details). The estimation methods give rise to a degree of climatic dependence in the DVI which should not be ignored. The present record contains no assessments based on temperature alone. The atmospheric circulation indices used are temperature-independent.

To examine relationships between volcanic activity, the atmospheric circulation and climate of the North Atlantic sector on timescales of 50 yr or more, non-overlapping 25-yr averages of the DVI, central England temperature[2] (CET) and a record of south-westerly surface wind frequency at London (B. M. Gray, East Anglia, unpublished data; pre 1728 figures are estimates) are used (Fig. 1). The latter is related to the character of the circumpolar westerly upper air flow as it crosses the North Atlantic, where it is determined by the strength, position and orientation of the Canadian upper air trough. These series were selected as they are the longest high resolution records of the atmospheric circulation and climate available for the North Atlantic sector. The degree to which they represent global events is difficult to assess in view of the limited availability of data for other sectors. Trends in CET over the past century are, however, similar to those observed in estimates of global or hemispheric temperature.

Fig. 1 25-yr Averages of *a*, winter temperature in central England; *b*, south-westerly wind frequency at London, provisional values pre-1728; *c*, volcanic DVI.

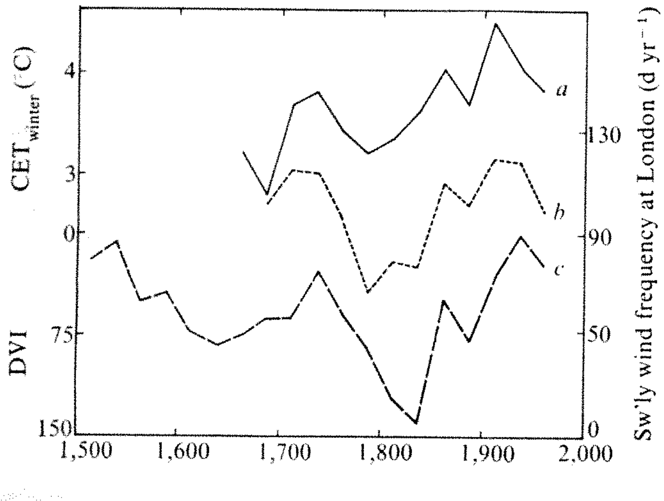

Table 1 lists correlation coefficients between the non-overlapping 25 yr averages of the three records for the period 1725 to 1950. The strongest relationships are between the DVI and the south-westerly frequencies (about 70% of the variance of the annual south-westerly record is explained by the DVI) and between the south-westerly frequencies and CET (about 80% of the $\mathrm{CET}_{\mathrm{w}}$ variance explained by the winter south-westerly frequencies). The input of large amounts of volcanic dust into the stratosphere affects the amount and distribution of solar energy reaching the Earth's surface, thereby influencing the strength of the atmospheric circulation. Lamb[1] showed that the frequency of the North Atlantic upper air westerly winds reduces on a year-to-year timescale following large explosive volcanic eruptions. The strength of these upper air westerlies, and the associated surface advection of air from southerly, oceanic sources, is a major factor in determining the winter temperature in central England and Western Europe.

Table 1 Correlation coefficients for the period 1725–1950 (nine pairs of non-overlapping 25 yr averages).

	DVI	$\mathrm{CET}_{\mathrm{\mu l}}$	$\mathrm{CET}_{\mathrm{winter}}$
DVI		−0.67*	−0.64
South-westerly frequency (annual)	−0.85*	+0.61	+0.86*
South-westerly frequency (winter)	−0.76*	+0.55	+0.90*

*Statistical significance above the 95% level.

Figure 1 shows that three major periods of stratospheric dust clearance have occurred on timescales of 50 yr and more, in the early sixteenth, eighteenth and twentieth centuries. These periods correspond to the maxima in the extended record of CET constructed by Lamb[3] from historical and botanical evidence. The effects of a minor clearance in the second half of the nineteenth century are also clear in the $\mathrm{CET}_{\mathrm{w}}$ and south-westerly frequency records (Fig. 1). Because of the relative shortness of the DVI record, the 200-yr interval between times of major dust clearance is considered fortuitous rather than evidence of a predictable cycle. A climatic cycle of about this length has, however, been frequently linked to solar variation[4,5]. Roosen *et al.*[6] proposed that this periodicity might result from regular changes in the moon's orbit. The associated changes in tidal stress could trigger volcanic activity and hence affect climate.

The varying level of volcanic activity explains much of the variation in CET on time scales of 50–300 yr but certain fluctuations present in CET are not seen in the DVI. Although the 200-yr periodicity is present in all three records, only $\mathrm{CET}_{\mathrm{w}}$ contains a linear trend (Fig. 1). This trend results from the recovery from the depth of the Little Ice Age which occurred during the second half of the seventeenth century. Neither the magnitude of the DVI, nor the reduction of the south-westerly wind frequencies is sufficient to account for this climatic severity. Although all three records must be considered suspect during this period, another climatic control, perhaps affecting

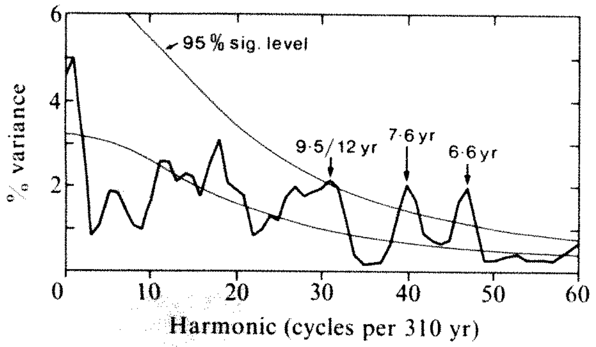

Fig. 2 Variance spectrum of the DVI, data for period 1500–1966. Calculated by taking the Fourier transform of the autocorrelation function, truncated at one-third of the data length. Red noise null continuum assumed as lag one autocorrelation coefficient significantly different from zero.

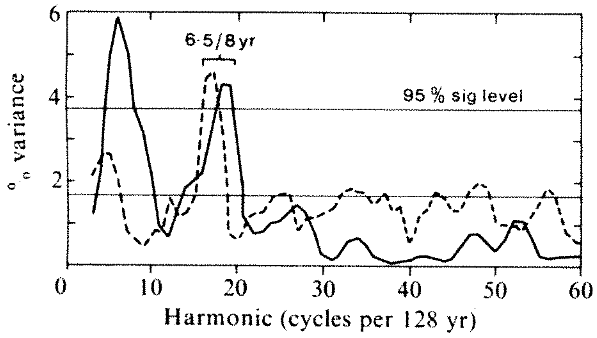
some other component of the atmospheric circulation, is required to explain the severity of this climatic shift. The low level of solar activity during the Maunder Minimum[7] of the seventeenth century may have been responsible. Solar particles emitted during solar flares seem to influence the strength of the meridional component of the North Atlantic atmospheric circulation[8,9], although the mechanism is unclear. The climatic effects of changes in the meridional circulation of the atmosphere are generally obscured as the zonal circulation exerts a stronger control over the UK climate[9]. Schneider and Mass[10] have modelled fluctuations in global temperature since 1600 employing fluctuations in volcanic and solar activity as climatic controls. In addition to solar variability, human activity may be a significant factor from the mid-twentieth century onwards.

Explosive volcanic eruptions inject into the stratosphere large quantities of volcanic dust which slowly falls out over succeeding years. This gives the annual DVI record a saw-toothed appearance: a series of impulses which gradually decay. Because of the damped response of the atmosphere–ocean system, a succession of fairly regular volcanic eruptions may result in an apparently cyclical climatic fluctuation. If volcanic eruptions occur with approximate regularity, a corresponding peak should appear in the variance spectrum of the DVI. If volcanic dust is an important climatic control, a similar peak may also appear in the spectra of climatic data for the same period. Matching peaks, however, do not necessarily show that volcanic activity and climate change in a regular, predictable cycle, the DVI periodicity may just be a chance characteristic of the data interval employed.

The variance spectrum of the entire DVI record is shown in Fig. 2. Three peaks are significant at the 95% level: at 9–12.5 yr, 7.6 yr and 6.6 yr. The peak at 9–12.5 yr is broad and, therefore, represents a process of highly variable period. It will not be discussed further. Bandpass filtering indicates that the two cycles at 7.6 and 6.6 yr are present through most of the period 1500 to 1966 but of low amplitude during the eighteenth century. They interfere to produce an amplitude modulated cycle with a wavelength close to 7 yr. The interval between periods of maximum amplitude is about 50 yr. The frequency and phase of the cycle are also variable. The fact that the parameters of the cycle (amplitude, phase, period, etc) are not constant places a considerable restriction on its forecasting potential.

Fig. 3 Variance spectra of the DVI (————), data for period 1850–1966, and the P index (– – – –), data for period 1861–1971. Calculated using the fast Fourier transform, to obtain similar resolution and avoid data loss.



The P index is a measure of the mobility of the flow of the atmospheric circulation over the UK on a day to day time scale[11]. In general, a high value of the P index indicates a period of mobile, westerly and cyclonic circulation types associated with vigorous North Atlantic westerlies. The variance spectra of this index and the DVI, calculated from available data for the period 1850 to date, are shown in Fig. 3. Both spectra contain a statistically significant peak at 7–8 yr. Considering the resolution of these spectra, the two peaks are indistinguishable in period. The variance spectrum of the CET record for the period 1816–1973 contains a similar peak but the earlier section of the record (1659–1815), comprising the eighteenth century when the 7 yr cycle in the DVI was of low amplitude, does not. Berlage[12] has discussed the apparently global extent of the 7-yr climatic cycle which is particularly marked in the El Niño phenomenon on the coast of Peru. However, many claims made for climatic cycles of any period are based on doubtful statistical analysis and require re-examination with modern techniques.

The volcanic cycle of 7 or 8 yr, and the associated climatic variation, may possibly be forced and, to a certain extent, predictable, as a similar fluctuation is present in parameters of the earth's rotation. Anderson[13], and Press and Briggs[14], have suggested that variations in seismicity, the two components of the earth's rotation (the rotational speed and polar motion) and the atmospheric circulation (and climate) could be linked. A fluctuation of 7 or 8 yr has been observed in modern measurements of the Earth's rotational speed[16], although the data interval is insufficient to test its statistical significance. Interaction between the annual component of the polar motion, forced by seasonal redistribution of the atmospheric mass, and the Chandler Wobble period of about 14 months gives rise to an approximately 7-yr fluctuation in the polar motion. The amplitude of the annual component also undergoes a 7-yr fluctuation[16]. It has been claimed that the polar motion could have a tidal influence on the atmosphere[16]. It is dangerous to discern cause and effect in such fragmentary evidence but the possibility that volcanicity, seismicity, the atmospheric circulation and the earth's rotation form a complex, interactive loop with a characteristic timescale of about 7 yr, perhaps determined by the period of the Chandler Wobble, cannot be neglected.

I am indebted to colleagues in the Climatic Research Unit for their comments. The research was supported by a Natural Environment Research Council Research Fellowship.

Oxygen isotope stratigraphy of Late Pleistocene coral terraces in Barbados

DISPUTE over the correlation of the last interglacial event in deep-sea cores with the corresponding shoreline feature on islands preserving fossil coral terraces has become a fundamental stumbling-block to progress in Pleistocene geochronology. If polled independently most scientists working in this area would agree that the last interglacial event is clearly recorded in their own data, yet the problem of precise correlation among the various types of data has remained the subject of controversy for the past eight years[1-8]. By making oxygen isotope determinations in molluscs collected from the Late Pleistocene coral terraces in Barbados, we have directly correlated these terraces with the oxygen isotope stratigraphic record of deep-sea cores, and have established that Barbados terraces I, II, and III (ages 82,000, 105,000 and 125,000 yr BP) were all formed during stage 5 of the standard oxygen isotope stratigraphy.

We will first review the data from interglacial highstands, and then that from interglacial sections in deep-sea cores. Pleistocene beach deposits are widespread on all the continents and on many islands; of particular interest are the latitudes of coral growth, within which Pleistocene sea-level stands are marked by fossil coral terraces. Aragonite coral skeletons are amenable to absolute dating using both the ^{230}Th/^{234}U method[9] and the ^{231}Pa/^{235}U method[10] within the time range Recent to ~ 150,000 yr BP. A large number of localities possess coral reef terraces which yield uranium-series dates in the region of 125,000 yr BP[4,11,12]. In tectonically stable areas, such as the Bahamas[13], Hawaii[14] and elsewhere, the 125,000 yr old terrace is found several metres above present sea level, and is the youngest pre-Holocene terrace present[9]. These data indicate that the 125,000 yr BP sea was above the present sea level, and that since that time the sea has been continuously below its present level.

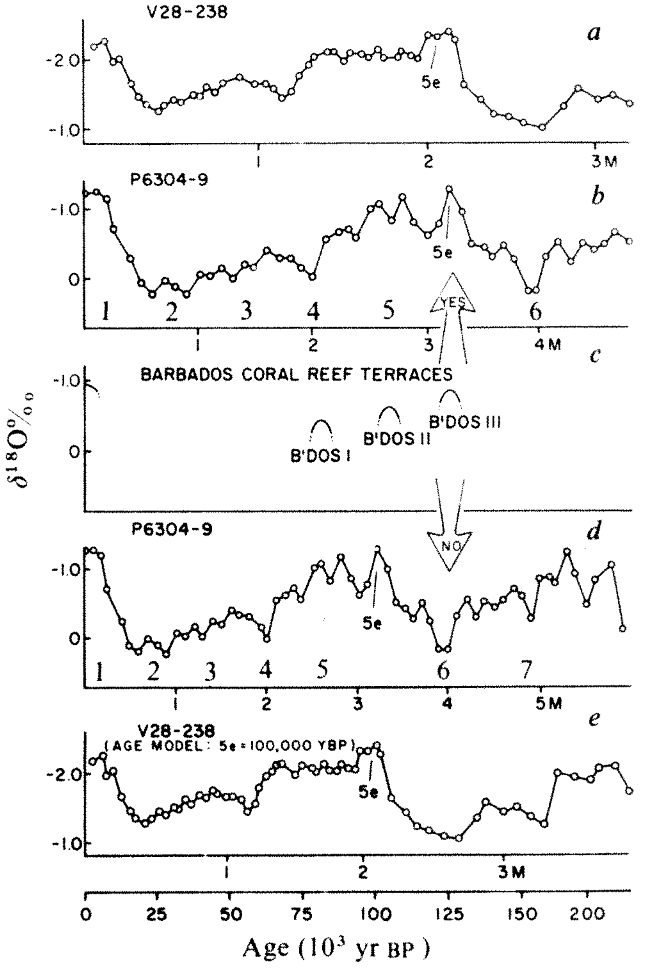
Coral reef sequences from tectonically emergent areas support the inference that subsequent sea level maxima have not reached the present level. For example, on Barbados, the Barbados III shoreline (125,000 yr BP) is well mapped and abundantly dated. Owing to tectonic uplift, the feature is presently at elevations ranging from 20 to 60 m; at lower elevations the Barbados II and Barbados I terraces are also mapped and dated[2]. Sea levels considerably below the present level have been estimated for these times by assuming a constant uplift rate calibrated by the present position of the Barbados III terrace. Similar studies in New Guinea on the tectonically emergent Huon peninsula lead to the same conclusion[15], as do studies in the Ryukyu Islands[11]. This implies then that the 125,000 yr BP terrace records the last interglacial in the sense that it formed the last time that continental ice volume was as small as it is today.

In deep-sea sediments, the oxygen isotopic composition of calcareous foraminifera has become a widely used stratigraphic tool. The oxygen isotope record has been divided into isotope stages whose boundaries can generally be easily recognised in all oceans[16]. Stage 5 was the last predominantly interglacial stage[3,4,17], within which the earliest substage 5e may probably be correlated with the last interglacial in a more strict sense as used, for instance, by palaeobotanists[3]. The stage 6–5 boundary, also known as Termination II[4], has been described as the most widely correlatable horizon in the whole geological column[18]. It is the age of this clearly-defined horizon, or of the equally clear interglacial event which followed it, that is a matter of contention.

One very persuasive line of reasoning, stems directly from the interpretation of the oxygen isotope record. It has been argued that the changing oxygen isotopic composition which is observed in foraminifera from deep-sea sediment cores, stems almost entirely from changes in the oxygen isotopic composition of the ocean itself, resulting from the storage of isotopically light water in the continental ice sheets[16,19-21], and hence may be an ice-volume or sea-level record. Clearly, if this is a correct interpretation, then there can be no doubt as to the correlation of the Barbados III terrace, with the earliest part of stage 5, which was uniquely interglacial in isotopic terms[3]. There are, however, reasonable arguments in favour of a smaller contribution to the oxygen isotopic record from this source[22], and if they are followed then the correlation of the Barbados III coral terrace with the early part of stage 5 is not a unique solution.

An alternative approach, of course, is the dating of the marine sediments themselves; this is the chief source of evidence for an alternative chronology. Beyond the range of ^{14}C dating, the uranium decay series may be used to date marine sediments. The application is less simple, however, than in the case of coral dating; there are difficulties in the analytical methods and acute problems regarding the interpretation of the measurements[24] which are widely acknowledged to exist. Several cores have yielded apparently consistent data which clearly point to an age near 90,000 yr BP for substage 5e[25]. Another core has been studied in considerable detail, and has consistently yielded an age near 120,000 yr BP for the same event[2,4,27]. Few other cores have been analysed in sufficient detail to contribute to a solution of the problem, and interlaboratory comparisons have so far only clouded the issue[28]. Thus, if correlation is to be based only on an absolute age estimation, a case may be made for correlating substage 5e either with the Barbados II or the Barbados III terrace.

Fig. 1 Oxygen isotope stratigraphy of Barbados coral reef terraces (*c*) compared with oxygen isotope stratigraphy of Caribbean core P6304-9 (*b* and *d*) and of equatorial Pacific core V28-238 (*a* and *e*). All five are plotted against a time axis; for the cores, depth in metres is also indicated. *a* and *b* are plotted assuming that the age of substage 5e is about 125,000 yr BP; *d* and *e* are plotted assuming that the age of substage 5e is about 100,000 yr BP. In *c*, the oxygen isotope data from this paper are plotted at the ages determined for the coral terraces from which our samples were collected. Data for *a* and *e* in refs 3, 4, 17 for *b* and *d* from ref. 31; for *c* from Table 1. The alternate timescales indicated respectively by *a* and *b*, and by *d* and *e*, are those depicted in Fig. 4 of ref. 8.



This dilemma, as well as other less substantial evidence, led Emiliani and Shackleton[8] to publish their infamous 'double curve' in which generalised versions of the isotopic record as a function of time were sketched for two different timescales through the last interglacial.

Clearly, the correct way to solve this problem is to make a direct stratigraphic correlation between the coral reef sequence and the deep-sea sediment sequence, instead of attempting correlation by means of age estimation. The coral terraces of Barbados contain molluscs which, like foraminifera, deposit their carbonate shells in oxygen isotopic equilibrium with sea-water[23]. Thus, the oxygen isotope record in a mollusc sequence should, in principal, be almost identical with the sequence observed through isotopic analysis of planktonic foraminifera in deep-sea sediments from the nearby ocean floor. Specifically, molluscs in the Barbados III terrace should be 0.1 ± 0.1 per mil more isotopically negative than those living today, if correlation with 5e is correct[3] and if 5e is therefore 125,000 yr old; they should be up to 1.8 per mil more positive if the terrace formed during the cold part of stage 6 (Fig. 1,) and 5e is correlated with Barbados II with an age of about 100,000 yr; they should be about 0.9 per mil more positive, with the age of 5e being about 90,000 yr, according to the correlation shown by Emiliani and Rona (they remark that molluscs in some raised beaches do give isotopically positive ^{18}O values suggestive of a glacial age—see ref. 7).

Molluscs were collected by R. K. Matthews from Barbados terraces I, II and III during summer 1973. Care was taken to collect only from reef front localities (predominantly *A. palmata* and *A. cervicornis* facies). By specifically avoiding lagoonal materials, we avoid the anomolous salinity and temperature conditions characteristic of that environment. Modern subtidal molluscs from Barbados were collected alive specifically for this study by Finn Sander (Director of the Bellaires Research Institute, Holetown, St James, Barbados W1).

Our first isotopic measurements on these materials was made in Cambridge[8] during 1974. Shells were sampled as described in ref. 30, and analysed in a VG-Micromass 602C mass spectrometer using the sample preparation system described in ref. 16. In the course of these determinations and subsequent investigation of the specimens in thin section, we became somewhat apprehensive about possible contamination by boring algae. We evolved a new sampling procedure. At Brown, molluscs were embedded in plastic, sectioned perpendicular to the shell wall and polished. An acetate film peel replica of the polished surface was prepared before and after sampling the shell with a small drill or with a tungsten carbide scriber. Examination of the peels with a light microscope allows detection of any areas of alteration or other abnormalities which may be avoided in sampling. Subsequent peels provide a permanent record of precisely what was sampled. We repeated the isotopic analyses at Brown University during 1975. The analytical methods used in the Benedum Stable Isotopes Laboratory at Brown University were similar to those used in Cambridge; again, a VG-Micromass 602C mass spectrometer was used. Results of these two independent studies are substantially in agreement. We report here only the second data set because we are confident that our new sampling procedure avoids contamination from boring algae.

Variation in average oxygen isotopic composition among Barbados Recent, Barbados I, II, and III are summarised in Table 1. We consider variation in average isotopic composition among these stratigraphic units to be primarily a measure of differences in global ice volume. We have, however, given detailed consideration to the possible contribution of temperature and salinity variations. The seasonal isotopic ranges measured are in good agreement with the range of values we observe in recent molluscs. The potential contribution of temperature and salinity to variation among the means is small. More importantly, these factors would also affect isotopic compositon of planktonic foraminifera from tropical deep-sea cores. As this paper deals with correlation of Barbados terraces to deep-sea cores by means of oxygen isotope stratigraphy, the precise origin of the signal which is common to the two data sets is of secondary consideration.

Table 1 Average oxygen isotopic composition of Barbados molluscs from Recent and Pleistocene terraces. Values are reported in standard notation relative to the PDB standard[23]

Stratigraphic level	δ^{18}O mean and standard deviation (‰)
Living Recent (17 analyses among 6 specimens)	−0.93 ±0.26
Barbados I (82,000 yr BP) (23 analyses among 9 molluscs)	−0.41 ± 0.41
Barbados II (105,000 yr BP) (16 analyses among 6 molluscs)	−0.62 ±0.40
Barbados III (125,000 yr BP) (16 analyses among 6 molluscs)	−1.04 ±0.55

One sample taken from one of the Barbados III shells yielded a value of +1.77‰, well over three standard deviations from the mean. We have not included the measurement in estimating the mean for this terrace. The observed standard deviation derives partly from seasonal temperature variation at the site; if average temperature varied with a standard deviation of ±1 °C this would give rise to oxygen isotopic composition varying with a standard deviation of ±0.2‰. Data will be submitted to the CLIMAP Data Base Management System at Brown University and subsequently archived with the National Geophysical and Solar-Terrestrial Data Center (NGSDC), Boulder, Colorado.

Figure 1 presents graphic comparison of the oxygen isotopic record of two deep-sea cores and the Barbados terraces in the time range 0–150,000 yr BP. Graphs *a* and *b* place isotopic substage 5e at 125,000 yr BP whereas graphs *d* and *e* place substage 5e at 100,000 yr BP. Graph *c* presents Barbados mollusc isotopic data from Table 1 and terrace ages as determined by ^{230}Th dating of corals from Barbados I, II, and III. Correlation of the Barbados data with graphs *a* and *b* is good, whereas correlation of Barbados data with graphs *d* and *e* forces correlation of isotopically light (interglacial) Barbados III with outrageously glacial conditions in deep sea cores. Thus, we conclude that isotope substage 5e must surely be correlated with Barbados III and must, therefore, in turn be correlated wtih the terraces elsewhere in the world which indicate a sea-level somewhat above present levels at around 125,000 yr BP. While geochemists may continue to discuss the relative precision of absolute age estimates obtained from coral terraces and from deep-sea cores, our data firmly establish the stratigraphic correlation between the two sequences.

Biological markers in coal and coal liquefaction products

ISOLATION of saturated isoprenoids from coal liquefaction products is an indication of the remarkable stability of these compounds. In the present investigation we show that some 'biological markers' and asymmetric carbons can survive the conditions of coal liquefaction without rearrangement or complete racemisation. Also, odd carbon numbered *n*-alkanes do not predominate, as reported for some coals, in either the coal liquefaction products studied or the feed coal. The distribution of saturates in the synthetic oil is very similar to that of some petroleums[1]. The detection of 'biological markers' in coal and coal liquefaction products supports the geological and chemical evidence that coal is a product of the progressive fossilisation of plant debris. Optically active materials isolated from peat, lignite, brown and bituminous coals corroborate this theory. Additionally, hydrocarbons bearing skeletal structures that are widely distributed among plants have been extracted from coal. Ōuchi and Imuta[2] have found normal alkanes from C_9–C_{31} in the benzene extracts of Yūbari coal; more recently, Harrison[3] and Bartle, *et al.*[4] have identified the normal alkanes and saturated isoprenoids in the supercritical toluene extracts of bituminous coals.

'Biological markers' are compounds which exhibit long term chemical stability to diagenesis and which also possess skeletal features related to biosynthetic sequences[5]. Compounds such as *n*-alkanes, iso-alkanes, anteiso-alkanes, isoprenoid alkanes, porphyrins, and long chain fatty acids show stability for long time periods in geological conditions and have been identified in coals[4,6], petroleums, oil shales, recent and ancient sediments[1], meteors, and oil sands. Also, the observation of optical activity among organic compounds is closely associated wtih their biosynthetic origins.

During an investigation of the saturate materials in coal liquefaction products, several classes of compounds that are biological markers were detected. The oil studied was produced by catalytic hydrodesulphurisation of coal at 450 °C and 300 atm pressure of hydrogen in a half-ton-per-day bench scale SYNTHOIL unit at the Pittsburgh Energy Research Center[7,8]. In this investigation, the solids in the gross liquid product were removed by centrifugation in the SYNTHOIL plant and the resulting liquid subjected to solvent separation using benzene and hexane[9] to yield a heavy oil constituting 60–70 wt % of the centrifuged liquid product. The heavy oil fraction was separated by the SARA[10] (saturates, aromatics, resins, and asphaltenes) technique to yield a saturate fraction which amounted to 6–7 wt % of the heavy oil. The saturate material was further separated on 5-Å molecular sieves[11] to yield *n*-paraffin and non *n*-paraffin fractions, 29 and 71 wt % of the saturate fraction, respectively. These fractions were then chromatographed and analysed by combined gas chromatography–mass spectrometry (GCMS).

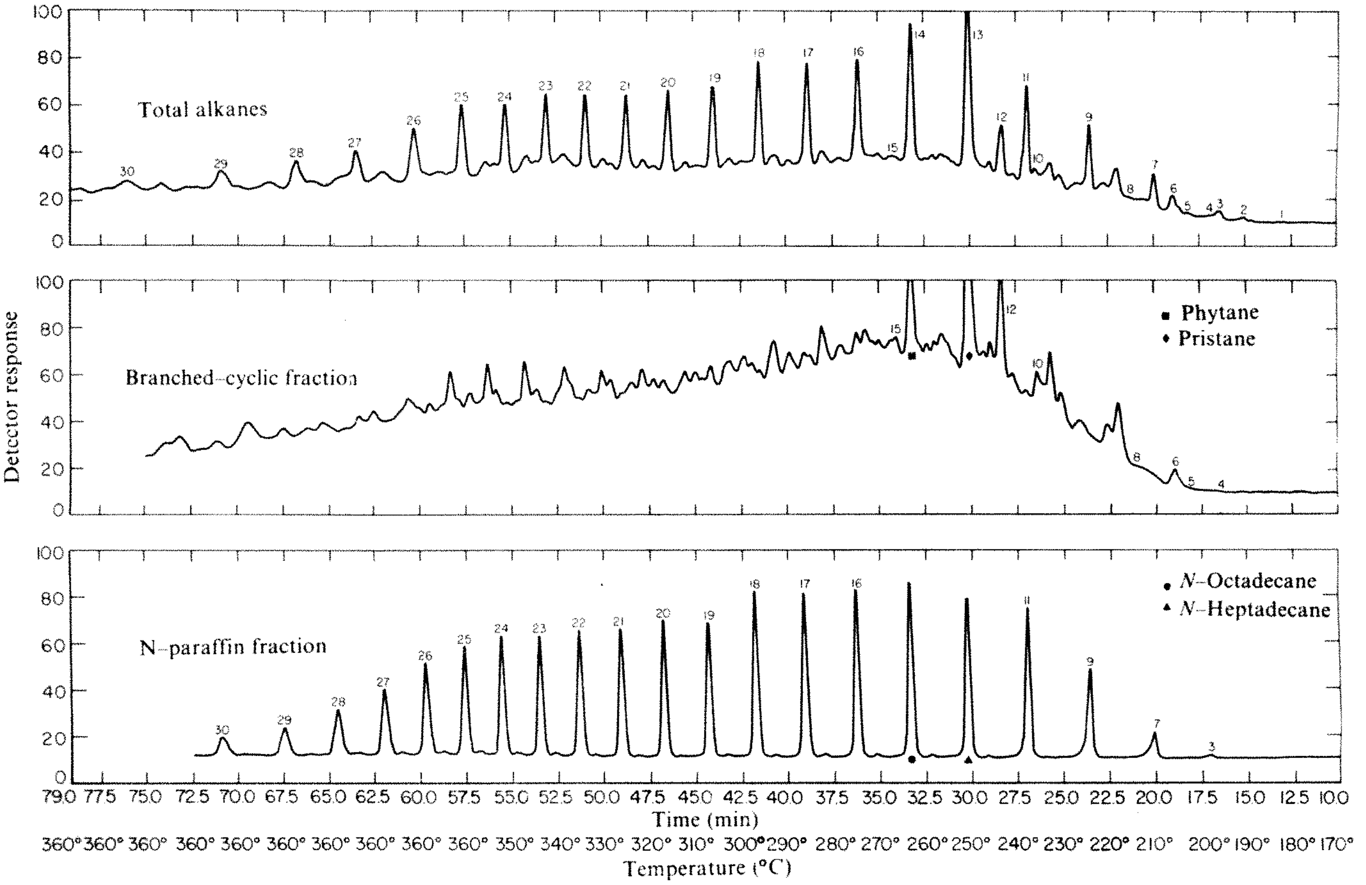

Fig. 1 The top chromatographic profile is of the total saturate materials isolated from coal liquefaction product. The middle and bottom chromatograms are subfractions of the total saturate materials separated by 5-Å molecular sieves. The combined GCMS analyses were performed with a DuPont 490 mass spectrometer interfaced to a Varian 1700 Series gas chromatograph, equipped with an 80:20 splitter and a flame ionisation detector, and to a Hewlett-Packard 2100A computer used for spectrometric data storage and reduction. The gas chromatographic separations were performed employing a 15 feet × ⅛ inch stainless steel column packed with 5% Dexsil 300 on acid washed Chromosorb-G at a helium flow rate of 30 cm^3 min^{-1} and appropriate temperature programming conditions. Each of the above chromatograms were run in duplicate. In all cases, the two chromatograms of the same material were identical.

Table 1 Analyses of the total saturate materials from a coal liquefaction product

GC peak number	Compound*	saturates† (mg per g)
1	*n*-dodecane	trace
2	C_6-cyclohexane‡	trace
3	*n*-tridecane	4.3
4	C_3-decalin	0.7
5	methylethyldecalin	1.1
6	cyclohexylcyclohexane	3.9
7	*n*-tetradecane	8.7
8	methylcyclohexylcyclohexane	0.9
9	*n*-pentadecane	12.0
10	perhydro-3-ring	1.4
11	*n*-hexadecane	13.4
12	C_{18}-isoprenoid	6.9
13	*n*-heptadecane and pristane	50.1
14	*n*-octadecane and phytane	38.7
15	perhydropyrene	3.6
16	*n*-nonadecane	17.2
17	*n*-eicosane	15.5
18	*n*-heneicosane	15.7
19	*n*-docosane	14.3
20	*n*-tricosane	14.3
21	*n*-tetracosane	12.2
22	*n*-pentacosane	11.5
23	*n*-hexacosane	12.2
24	*n*-heptacosane	10.1
25	*n*-octacosane	10.7
26	*n*-nonacosane	10.4
27	*n*-triacontane	9.0
28	*n*-hentriacontane	8.9
29	*n*-dotriacontane	5.3
30	*n*-tritriacontane	3.4
		316.4 mg

*Personal communication, D. M. Jewell: many of the low boiling materials are lost during the solvent removal steps of the SARA fractionation. The loss is essentially zero for hydrocarbons of 15 carbons and above.

†The quantity of the various hydrocarbons listed is approximately within ±20% of the amount shown.

‡Indicates the number of alkyl carbons as substituents on the ring.

The chromatographic profiles of the saturate materials isolated from the coal liquefaction products before and after separation into two fractions on 5-Å molecular sieves are shown in Fig. 1; the identifications of the various numbered chromatographic peaks are given in Table 1. Inspection of the chromatographic profile of the *n*-paraffin fraction from the coal liquefaction product indicates that the odd carbon numbered *n*-paraffins do not predominate over the even. The carbon preference index[1], CPI, calculated using mole per cent data obtained from the chromatographic profile of the *n*-paraffin fraction equals 1.08. The *n*-paraffins are equally distributed between odd and even carbon numbered homologues. Others[12] have shown that thermal alteration of organic sediments causes elimination of any carbon numbered preference. Thus, if the feed coals contained *n*-alkanes having a large predominance of odd carbon numbered homologues, liquefaction could eliminate this predominance. Preliminary data indicate that the distribution of *n*-alkanes in this coal liquefaction product is similar to their distribution in some petroleums[1].

A sample of the feed coal, 364 g, used in the liquefaction process (Ireland Mine, W. Va., hvAb) was extracted in a soxhlet using benzene, in order to show that some of the *n*-paraffins found in the liquefaction product were originally in the feed coal. The benzene was removed from the extract by freeze drying, yielding 1.72 g of solids. This solid was batch extracted with *n*-pentane and centrifuged, yielding 1.29 g of pentane soluble material. The pentane soluble material was batch washed through silica gel (Brockman Activity I, 70–230 mesh), yielding 0.33 g (0.99 wt % of original coal) of non-silica gel-absorbed material. The pentane-soluble, non-silica gel-absorbed material was analysed for the *n*-paraffins by combined GCMS. The chromatographic profile and identification of the normal paraffins is shown in Fig. 2. Inspection of this chromatogram indicates that odd carbon numbered *n*-paraffins do not predominate over even. The *n*-heptadecane peak also contains pristane. Ōuchi and Imuta's[2] data, CPI ~1.09, indicate that there is no predominance in Yūbari coal and thus, is in agreement with the results obtained in this investigation, while the recent work of Bartle, *et al.*[4] indicates that there is a predominance of odd over even carbon numbered *n*-paraffins in the bituminous coal they studied. Leythaeuser and Welte[13] have clearly shown that, in the case of coals from the Upper Carboniferous of the Saar district, the predominance of odd over even carbon numbered *n*-paraffins decreases with increasing coal rank. This explains why the results among different workers concerning the predominance of odd over even carbon numbered *n*-paraffin homologues in coal seem to disagree. Bartle, *et al.* investigated a low rank coal (NCB Coal Rank Code 802) while the coals investigated here and by Ōuchi and Imuta were high rank bituminous. The work of Leythaeuser and Welte included only coals of specific European origin and, therefore, a more comprehensive study involving many coals from different continents is needed to determine whether the correlation between *n*-paraffin distribution and coal rank can be generalised.

In addition to *n*-alkanes, discussed above, another class of biological markers found in coal liquefaction products is the saturated isoprenoids—pristane, phytane and a C_{18} isoprenoid were identified. The precursors of these hydrocarbons are unknown, but it is surmised that they result from the diagenesis of phytol, a moiety widely distributed among plant pigments. Phytane and pristane are known to be in coals[2,3]. Thus the saturated isoprenoids and normal paraffins found in coal liquefaction products may be from two sources: (1) formed during the liquefaction process from a precursor having the same or similar carbon skeleton, or (2) are present in the feed coals as entrained alkanes extractable by benzene, survive the liquefaction process, and go into the liquefaction product.

The optical activity of the saturate fraction from a coal liquefaction product was investigated and was found to rotate plane polarised light, $[\alpha]_D^{25} = +0.340°$. The low degree of optical rotation is possibly a consequence of the partial racemisation of many enantiomers during the liquefaction process. It is interesting that the saturate fraction was dextrorotatory. Zahn, *et al.*[14,15]

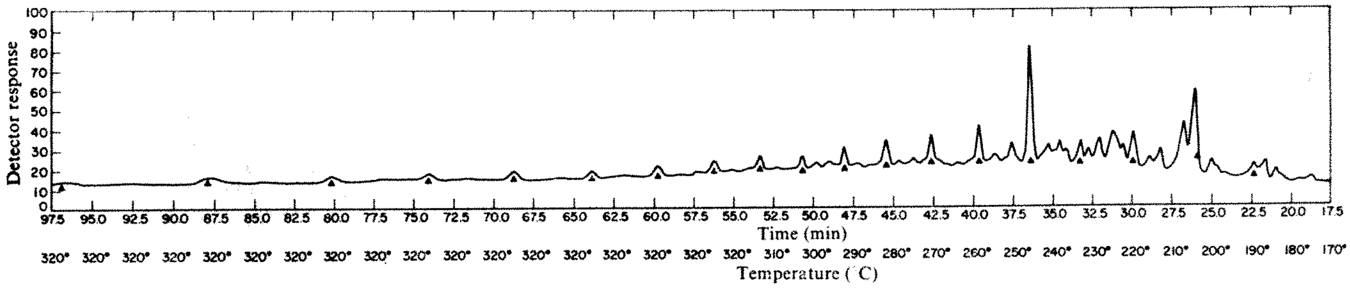

Fig. 2 Chromatographic profile of the pentane-soluble, non-silica gel absorbed material obtained from the benzene extraction of hvAb coal. The starred peaks indicate the *n*-paraffins. The first such labelled peak is *n*-tridecane, the second is *n*-tetradecane, and so on. The analysis was performed using the same equipment and conditions described in Fig. 1. This material was gas chromatographed twice to minimise errors in sample handling. Both chromatograms were identical.

showed that the distillates from coal hydrogenation products and carbonisation tars from Pittsburgh seam coals showed positive rotation only. Hydrogenation oils produced from other coals displayed various positive and negative rotations but the distillates having positive rotation were far more numerous than those having negative rotations[14,15]. Mair[16] has made the same observation concerning petroleum distillates.

We are grateful to Nestor J. Mazzocco and Sayeed Akhtar of the Exploratory Engineering Group at PERC for providing the coal liquids used in this study. We gratefully acknowledge the contributions of Frank Schweighardt and Fred Karn who supervised the solvent separation of the liquefaction product and coal extracts. The optical activity measurements were made through the courtesy of Rudolf Laboratory. The SARA and molecular sieve separations were carried out by Gulf Analytical Services, Harmarville, PA.

Stratigraphy of buried soil at Teindland Forest, Scotland

EDWARDS *et al.*[1] have described and discussed new palynological and fabric analyses which have made an important contribution to our understanding of the stratigraphical history of the unique buried soil at Teindland, first described and dated by Fitzpatrick[2]. Since 1962 detailed information relating to the distribution and periglacial modification of glacial deposits in the vicinity of Teindland has been gradually accumulated during the soil survey of the area represented on Sheet 85 (Rothes)[3]. Here we relate these field observations to the stratigraphy of the buried soil section at NJ 297570, and obtain a rather different interpretation of the nature of the 'sandy till' described by Edwards *et al.* as overlying the buried soil, and of the general stratigraphy of this site.

The summit area of Teindland Forest and the east facing slopes are covered by till and solifluction deposits derived from sedimentary rocks of Middle and Upper Old Red Sandstone age with some admixture of acid schists in the till at the southern end of Teindland Forest. Along the lower edge of the east facing slope there are scattered remnants of sandy and gravelly lateral moraine mostly lying above the line of the B9015 road. Between junctions at NJ 311522 and NJ 309550 this road also marks the approximate upper edge of the highest fluvioglacial terrace of the Spey Valley.

Above about 185 m no frost cracks are present in the compact red till exposed in profile pits and natural sections. On the eastern sideslopes the till is generally overlain by a very variable blanket of coarse textured stony solifluction deposits and below 120 m distinctive grey frost cracks with ochreous edges are present in the till. This distribution pattern has been confirmed at Wood of Cairnty on the east side of the Spey Valley. In sections alongside a forest track at about 165 m only the remnant basal tips of frost cracks can be seen, whilst downslope in a roadside cutting at about 125 m well-developed frost cracks are present in red till which is buried below a surface layer of solifluction debris. Most of the localities around Teindland where frost cracks or wedges have been recorded during soil survey are listed in Table 1.

From the field evidence it is clear that at some time after the deposition of the local red till there was a period of intensely cold periglacial climate during which a fairly uniform pattern of frost cracks and wedges was developed over the local landscape. Subsequent denudation of the hilltops with downslope migration of solifluction debris was not necessarily restricted to one episode. There is considerable evidence[4,5] for widespread solifluction and erosion in Scotland during the period of the Loch Lomond Readvance (Pollen Zone III)[6] and local evidence of some later erosion in the form of footslope accumulations of sandy gravel and colluvium above a peat band containing a late Sub-Boreal pollen assemblage at Bogincur farm (NJ 307554).

The pit face at Teindland has eroded considerably since it was first described. As exposed in 1962 the organic horizon, subsequently ^{14}C dated at 28,140+480 and −450 years b.p. (NPL−78), had the form of a solifluction lobe cut through by a number of stepped frost cracks (Fig. 1). Only a limited part of the buried organic A horizon remains and on the longer backslope face of the pit the buried soil is represented by a layer of yellow-brown sand derived from the B horizon.

Thin sections prepared from the organic horizon in 1965, 1967 and 1976 consistently show that the organic material is heavily charred and contains coniferous charcoal closely resembling *Pinus sylvestris* charcoal prepared from wood recovered from a 'Grentz' horizon[7]. The presence of (burnt out) pine wood in this context may be indicative of the onset of colder climatic conditions[8]. The charred nature of the organic horizon and the distinctive sandy infill of the cracks suggests that the sand above the organic horizon was deposited soon after the fire. Photographs taken in January 1977 show clearly that this sand layer constituted part of the curved front of a solifluction lobe low down on the eastern side of the present section and was therefore deposited before this lobe formed. The size of the frost crack steps relative to the size of the solifluction lobe (Fig. 1) indicates some movement of the lobe before as well as after the formation of the cracks, so that permafrost was already present before the cracks formed. West[9] has noted that temperatures around −6 to −8 °C, considerably lower than the temperature required for the promotion of permafrost, seem to be necessary for the formation of frost wedges. The surviving part of the buried H horizon seems to owe its preservation to rapid burial (at a break of slope) under sand eroding from the A and B horizons of the surface immediately upslope, a cover which was rapidly consolidated by the subsequent rise of the permafrost table. The material overlying the organic layer, described as 'sandy till' by Edwards *et al.*[1], is similar to but slightly coarser in texture than, the red till generally encountered in profile pits close to this site (Table 1). The very variable nature of this deposit which has been revealed over a period of years and the included irregular sandy lenses are not typical of the local red till. The

Table 1 General distribution of periglacial phenomena around Teindland, range in clay content of the local red till and clay content of soliflucted till above the approximately 28,000 years b.p. organic horizon at Teindland.

Site name	Description	Grid reference	Altitude* (m)	Presence/absence of frost cracks/wedges	Clay content of till (%)
Findlay's seat no. 1	Profile pit	NJ 283 537	260	Frost cracks absent	10–16
Teindland forest no. 1	Profile pit	NJ 289 548	240	Frost cracks absent	11–17
Teindland no. 2	Profile pit	NJ 300 529	185	Frost cracks absent	≈14
Teindland seed beds	Profile pit	NJ 295 569	125	Frost cracks present 38–104 cm+	≈20
Clatteringbriggs wood	Profile pit	NJ 290 581	85	Frost cracks present 48–118 cm+	12–15
	Test hole	NJ 296 580	85	Frost cracks present below 33 cm	–
Red burn	Bank section	NJ 302 576	75	Frost cracks present 56–180 cm	–
	Gravel pit	NJ 310 552	60	Several frost wedges present	–

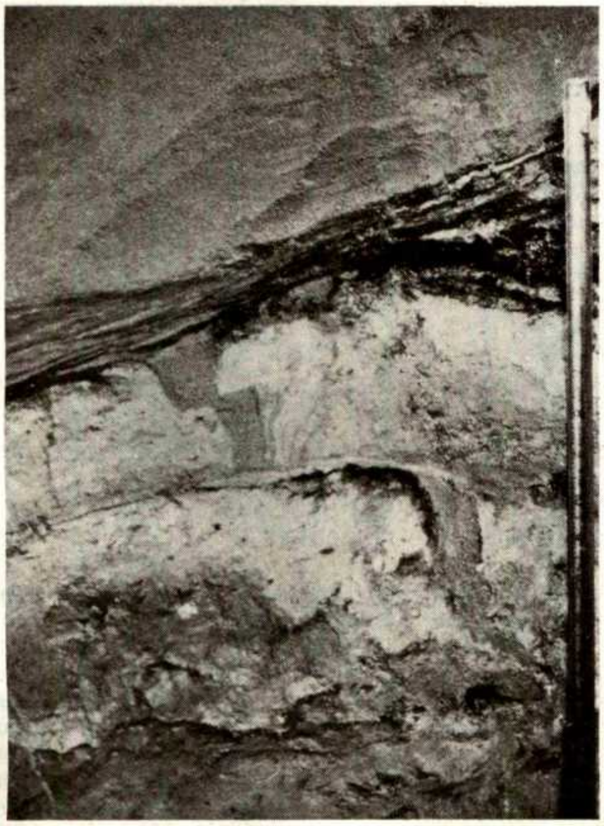
Buried soil section at Teindland	Quarry pit	NJ 297 570	100		7–9

*Altitudes estimated to nearest 5 m by interpolation between contour lines of Ordanance Survey 1:25,000 scale map.

absence from this deposit of a regular pattern of polygonal frost cracks as seen in the red till in nearby exposures along the Red Burn (Table 1) (which would clearly have been just upstream of the Teindland site during any Devension glaciation) confirms that this 'sandy till' is in fact soliflucted till and lateral moraine derived from the nearby slopes of Teindland Forest. This interpretation is consistent with both the pollen data and particle size and shape criteria indicative of glacial origin presented by Edwards *et al.* The preferred orientation of pebbles of 110–120° measured by Edwards *et al.* is not in accordance with the orientation to be expected from free downslope flow of a solifluction deposit[10], but it should be pointed out that this measurement was made only a few metres from the position at which the downflow must have stopped at the change of slope. Pebble orientation at this point is, therefore, unlikely to be in the direction appropriate to unconfined free flow, and orientation in concordance with ice flow direction is coincidental.

Fig. 1 Detail of the largest frost crack present in the 1962 section at Teindland.



Climatic data presented by Dansgaard *et al.*[11] show that the period 28,000–12,000 b.p. was the most prolonged cold interval during the Devensian stage. The strong indications that the till-like material above the buried organic horizon at Teindland is a solifluction deposit and the probability that the frost cracks in the buried layer are contemporaneous with those developed in red till sections around the site suggest that the age of deposition of the local red till is pre-Devensian, and that Devensian sheet glaciation in this area is improbable.

I thank Mr J. Logan of the Macaulay Institute for the mechanical analyses in Table 1, Dr S. E. Durno of the Macaulay Institute for pollen analyses of the Bogincur farm buried peat and Mr J. Atterson of the Forestry Commission who took the photograph reproduced in Fig. 1.

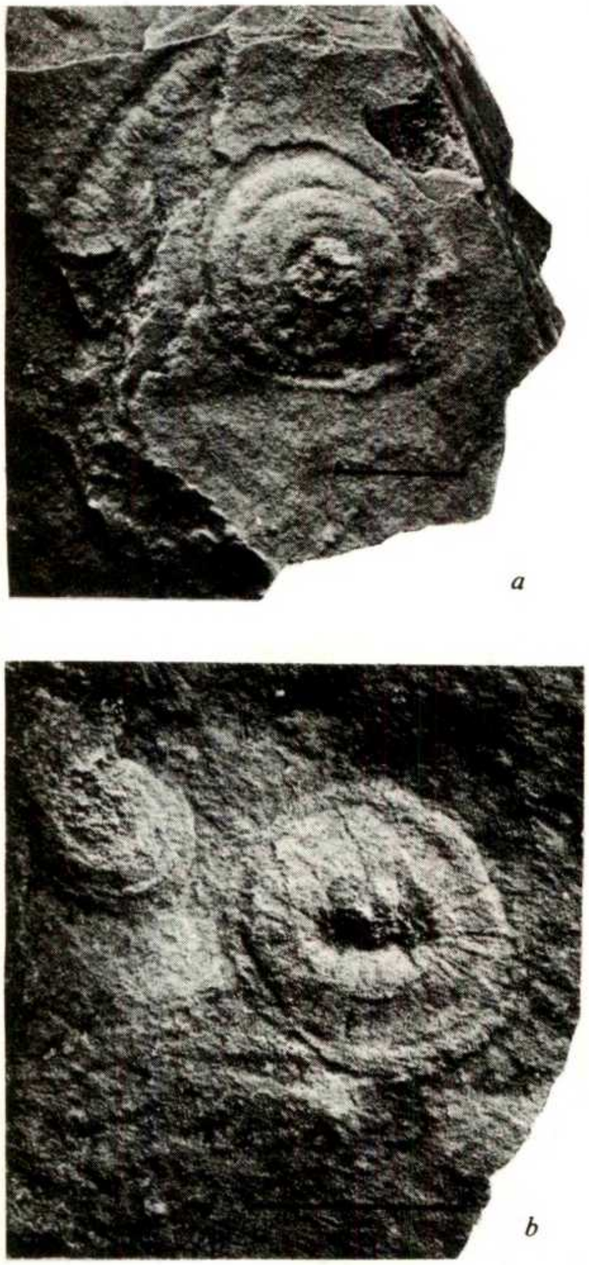
An Ediacara-type fauna from South Wales

DURING investigation of the geology of the area south of Carmarthen, South Wales, UK, an isolated small exposure of a finely inter-laminated mudstone and siltstone of possible volcanogenic origin was discovered. This lithology differs from those found hitherto in the Arenig and Old Red Sandstone rocks locally, and does not resemble any of the facies of the recently discovered Tremadoc rocks of the area[1]. Samples from this quarry were examined by K. J. Dorning of Sheffield University for microflora, but yielded none. Late last year a few badly preserved disk-shaped impressions, some 1 cm in diameter, were discovered. These were tentatively linked with the trace fossil *Astropolithon* by P. Crimes (Liverpool) and A. Seilacher (Tübingen), who both suggested that if the material proved to be *Astropolithon* an Early Cambrian age would be indicated.

Fig. 1 In each case, scale bar equals 10 mm. *a*, *Cyclomedusa* sp. *b*, *Medusinites* sp.



Further searches were made in the hope of finding material useful for dating. These have now yielded about 50 specimens including some better preserved material which is clearly of medusoid nature. A few of these specimens were subsequently examined by I. P. Crimes and by R. Jenkins (Adelaide), who both confirmed the medusoid nature of the fossils and suggested that they included a form occurring in the late Precambrian Ediacara fauna of South Australia.

Amongst the material so far collected, the genera *Cyclomedusa* Sprigg 1947 (ref. 2) and *Medusinites* Glaessner and Wade 1966 (ref. 3) have been identified. The less well preserved material includes a form resembling the genus *Tribrachidium* Glaessner 1959 (ref. 4). Others cannot at the moment be related to any previously described forms.

The fauna clearly carries elements characteristic of the Ediacara fauna. Late Precambrian soft-bodied organisms are known from various areas of the world[5] including Charnwood Forest, Leicestershire, UK[6]. In the Carmarthen region, however, until recently the earliest known rocks were of Early Ordovician (Arenig) age. The discovery of Tremadoc rocks there has led to a re-assessment of the age of the underlying rhyolites which are now presumed to be Precambrian. The rocks which have yielded the medusoids appear to rest on the rhyolites, although field relations in such a poorly exposed area are not clear.

No Cambrian rocks (if one excludes the Tremadoc) have hitherto been found in this area, and the possibility that the fauna is of Cambrian age cannot be excluded. It is felt, however, that the absence of any similar fauna in the Cambrian rocks of the St David's area (or elsewhere in Wales), argues against this, as does the apparently complete absence of metazoan skeletal material which would be most unusual for shallow water Cambrian sediments. Glaessner[5] has given reasons for assigning a late Precambrian age to the Ediacara fauna. On palaeontological as well as regional geological grounds a similar age is suggested for this fauna.

Details of the location of the exposure and a description of the fauna will be published after a full investigation of the site.

Tachigalia versicolor is a suicidal neotropical tree

WITHIN a year of flowering in *Tachigalia versicolor* Standl. and Wms (Leguminosae-Caesalpinoideae) the leaves drop, the fruit is released and the tree dies. Reproduction occurs synchronously at intervals of several years in this large, much-branched, canopy tree species, but not all of the large individuals in the forest canopy flower and die at once. The species is known from the evergreen and semi-deciduous lowland forests of Panama, south-east Costa Rica and north-west Colombia. Except for a brief mention[1] of the Amazonian *T. myrmecophila*, I have found no previous reference to reproduction followed by death in *Tachigalia* (including *Sclerolobium*, an apparently congeneric taxon[2,3]), nor in any other large, branched, dicotyledonous tree. My preliminary observations in Peru suggest that this behaviour is characteristic of several of the other 56 species in this genus, most of which occur in the Amazon Basin.

For 10 yr, *T. versicolor* trees have been watched on Barro Colorado Island, Panama, a field station of the Smithsonian Tropical Research Institute in the centre of the Panama isthmus. Initially, nearly 40 individual trees were known and mapped though not tagged. In the past 3 yr a search has revealed 430 trees, and these have been mapped and marked with metal number tags.

From 1967 to 1969, no reproductive individuals were observed. But in 1970 at least 18 large trees flowered. All died within 1 yr, after release of their wind-dispersed fruits. No vegetative regrowth has been observed from the bases of trees or underground parts.

After 1970, no further flowering was seen for 4 yr. In 1974, eighty-five individuals were found in full flower on the island and all were dead by May 1975 (Fig. 1). This represents approximately one-fifth of the 430 known canopy trees. The non-reproductives completely overlap the range of sizes (height and diameter) of the reproductives (Fig. 2). Stem growth-rings are not distinct and the age of individuals at reproduction is not known.

Though the two flowering waves were distinct, the individuals flowering within a given year were not closely synchronised in the initiation of flowering. Some started flowering as early as January (the dry season) and others as late as July (the rainy season). Individual flowering lasts between 3 and 6 months. As a consequence, the flowering period for the whole population lasts almost a full year.

Two trees initiated flowering in 1975. One had its roots naturally grafted to those of an adjacent tree that had flowered in the previous year, and the second was a sickly individual with one branch remaining. No trees were observed to flower in 1976. There were a few partial exceptions to the rule of death following reproduction in 1974: three individuals produced flowers and fruits on only a few of their branches; those branches subsequently died, but the trees as a whole survived.

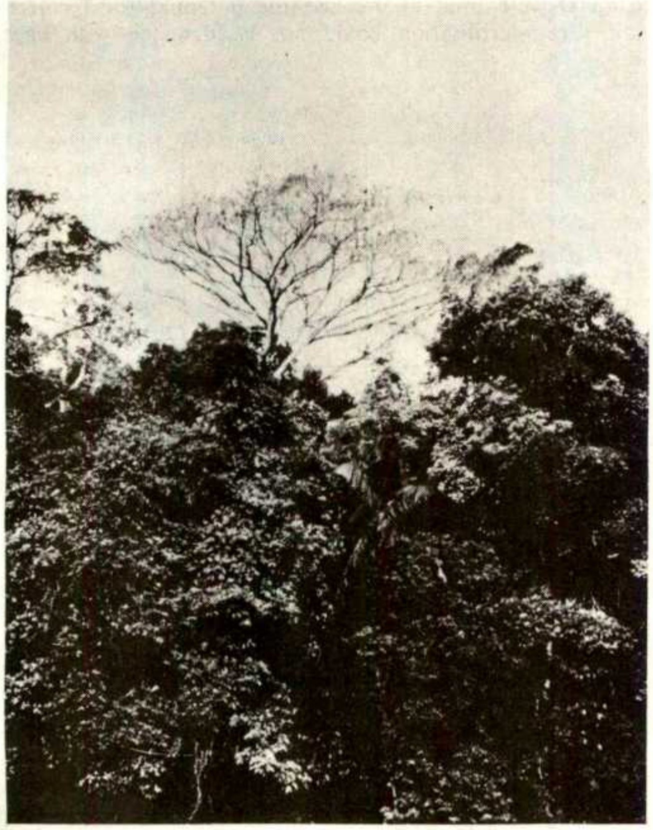

Fig. 1 View of dying emergent *Tachigalia versicolor* on Barro Colorado Island from Gatun Lake, Panama, February 1975. A few fruits remain on the estimated 7,000 terminal inflorescences. As flowering finishes, the leaves drop off, leaving the canopy crowded with 15-cm fruits that are green and leaf-like. These turn brown and are dispersed by wind in the January–April dry season, as the trunk starts to decay.

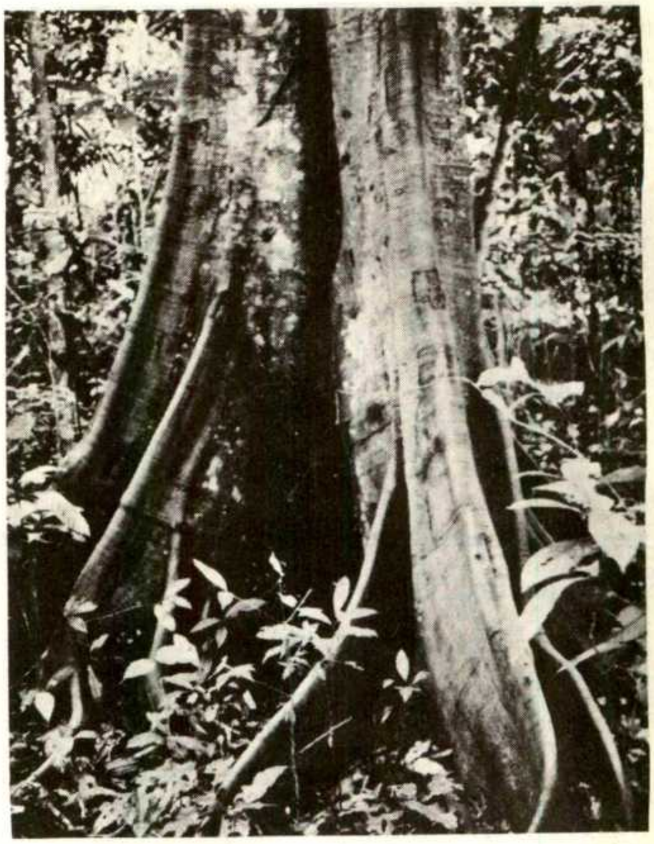

Fig. 2 Trunk of non-reproductive *Tachigalia versicolor* Leguminosae-Caesalpinoideae. Diameter at breast height was 116 cm and height was 35 m. Individuals of both reproductives and non-reproductives are commonly more than 150 cm and 40 m in height.

A suicidal act of reproduction might seem maladaptive for a species of huge trees. These trees do not seem to store nutrients and energy for the one reproductive event, for the quantities of flowers and fruits seem no greater than in comparably sized tree species with repeated reproduction. On the basis of initial observations, I propose that selection has favoured individuals which, by dying and falling, greatly increase the probabilities for their few progeny of survival to maturity in the forest canopy. The parent's death creates a more favourable environment for the development of its offspring, and occurs when the offspring are still abundant—having not yet succumbed to all the sources of juvenile mortality. Because most, if not all, tropical canopy species require an opening or 'light-gap' in the forest canopy for successful maturation[4,5], a treefall should strongly augment the opportunities for seedlings in the vicinity of the parent. As with other species that have large wind-dispersed propagules, the seeds and seedlings of *T. versicolor* are rarely found more than 100 m from the parent. Thus most seedlings (when not completely crushed) are likely to be exposed by the fallen parent, or by nearby treefalls resulting from the initial disruption of the forest canopy. *T. versicolor* saplings are often found growing in the openings directly created by the fall of an adult, or in adjacent openings. The rate of growth (or some other important parameter) of the trees I observed could be augmented by the amount of energy and nutrients they do not put into reproduction every year.

This work was supported in part by the Smithsonian Tropical Research Institute, a NSF traineeship at Duke University and the Hutchinson Fund of The University of Chicago. I thank E. G. Leigh, C. Gyllenhaal, N. Garwood and S. Hopson for comments; W. A. Rodrigues, J. Mulroy, A. R. Kiester, A. S. Rand and my graduate students for helpful discussions, and N. Garwood, D. Watts and S. Hopson for field assistance.

Cross-fertilisation in fucoid seaweeds

EXPERIMENTAL studies on the extent of cross-fertilisation between eggs and sperm of various fucoid seaweeds are few, the results widely divergent and in no case have the experimental conditions been precisely defined. For example, in interspecific crosses between *Fucus serratus* eggs and *Fucus vesiculosus* sperm, values of 0%, 2% and 91% have been recorded (refs 1, 2 and 3 respectively). Hybridisation to a greater or lesser extent on the shore does, however, seem feasible especially since many species are cytologically identical[4]. Indeed, plants showing morphological features intermediate between parental types have been recorded[5,6]. While some authorities[7,8] consider that intermediate forms represent no more than ecotypes or phenotypic variants of parental type species, others[3] consider that these represent true hybrids, although cytogenetic evidence is lacking. We report here a re-appraisal of the specificity of cross-fertilisation between three fucoid seaweeds. The results show the presence of inherent interspecific and inter-generic barriers to fertilisation. But, interspecific hybridisation may be permitted following the breakdown of these barriers.

Fucoid eggs secrete a polysaccharide cell wall immediately after fertilisation[10,11]. Accordingly we have used the fluorescent brightener Calcofluor white ST (Cyanamid) to stain zygotes permitting a rapid and direct assessment of the level of fertilisation by ultraviolet microfluorescence (Reichert Diapan microscope fitted with exciter filters BG38 and UG1 and barrier filter GG13+W2B). It has been determined that zygotes which stain positively with Calcofluor subsequently show rhizoid development.

Fertile plants of *Fucus serratus, F. vesiculosus* and *Ascophyllum nodosum* were collected from several localities on the west coast of Anglesey, Wales during April 1977, and stored moist for up to 7 d. *Ascophyllum* was included in view of a report[9] that sperm of this plant can cross-fertilise eggs of *F. vesiculosus* to an extent of 4%. Dioecious species only were chosen for this study since it was considered imperative that any possibility of cross-contamination of gametes should be avoided.

Gametes were released[10] when required and crosses were carried out by incubating 5,000 eggs in concentrations of sperm up to 4,000 per egg, in a total volume of 2 ml for 20 min at 18 °C. Sperm were inactivated by adding 20 μl of 0.2% I_2 in 2% KI and the excess liquid removed from the eggs which had been allowed to settle. The eggs were washed once with seawater and then incubated for 5 min in a saturated solution of Calcofluor in seawater. After removing excess Calcofluor the eggs were washed in seawater once more, then percentage fertilisation was assessed by counting the number of eggs showing the characteristic fluorescence in a sample of 200 eggs. Control incubations omitted sperm.

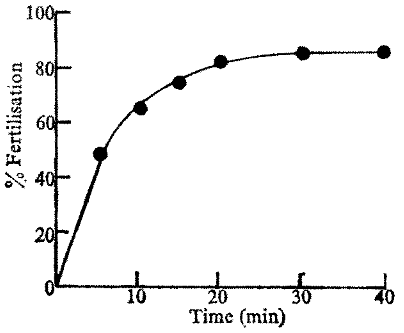

Fig. 1 Time-course of homologous fertilisation in *Fucus serratus.* 5,000 eggs were mixed with 200 sperm per egg.

Homologous fertilisation in the three seaweeds has similar characteristics with regard to the kinetics of fertilisation and fertilisation efficiency. Fertilisation can be detected within a few minutes of adding sperm but is essentially complete within 20 min (Fig. 1). Fertilisation efficiency is linear at low sperm concentrations, 50% of eggs being fertilised at relative sperm concentrations between 50 and 100 sperm per egg, saturation being approached between 250–500 sperm per egg (Fig. 2*a,e,i*). Efficiency of homologous fertilisations is independent of the stored age of either male or female plants up to 7 d in the experimental conditions used.

In heterologous fertilisations sperm to egg ratios of up to 4,000 were used to increase the potential for fertilisation. Cross-fertilisation could not be detected with eggs

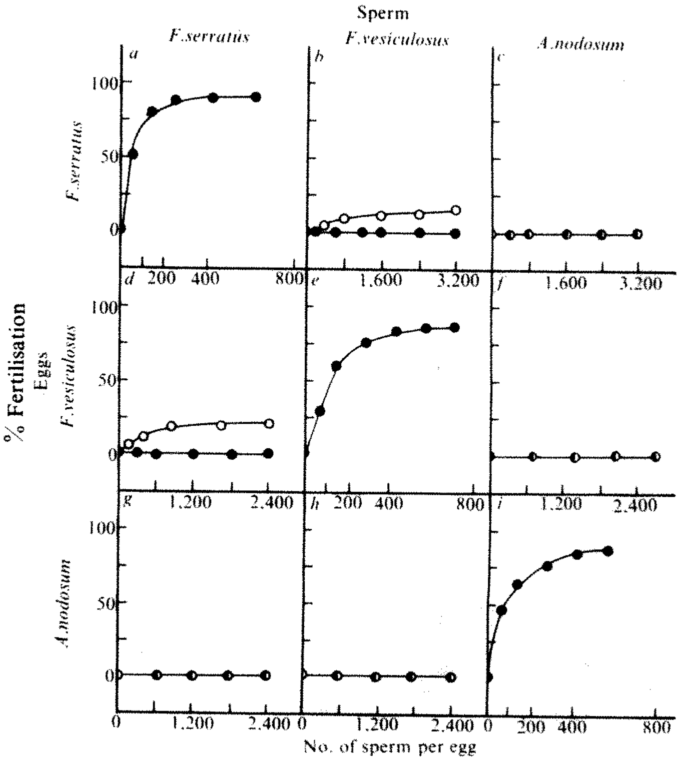

Fig. 2 Fertilisation efficiencies in homologous and heterologous fertilisations. 5,000 eggs were incubated with different concentrations of sperm. ●, Eggs from freshly-collected plants; ○, eggs from 4–5 d stored plants; ◐, eggs from freshly-collected or stored plants.

released from freshly collected plants in any of the six crosses shown in Fig. *2b–d,f–h*. But, in the case of *F. vesiculosus* eggs × *F. serratus* sperm, or the reciprocal cross, low levels of fertilisation were detected up to 20% with eggs freshly released from plants stored for 5–7 d (Fig. *2b,d*). Storage time of male plants was immaterial.

The inter-generic crosses between the two *Fucus* spp. and *Ascophyllum* were negative in all conditions of storage and sperm concentrations used. The occurrence of cross-fertilisation between *F. serratus* and *F. vesiculosus* was subsequently confirmed by the occurrence of segmented zygotes in samples incubated for 24 h.

Fucoid seaweeds show a wide range in form in response to environmental factors[12]. In addition, hybrids have been described and on the basis of ecological observations and hybridisation experiments it has been concluded that there are no inherent sterility barriers among *Fucus* species and that the barriers which prevent the merging of the different species into one polymorphic complex are ecological rather than physiological, related, for example, to non-coincidence of fruiting periods[3] and competition from parental forms[2]. The results of our investigation do not support this conclusion, since direct studies on fertilisation showed that there are inherent barriers to both inter-generic and inter-specific cross-fertilisation. But, the interspecific barriers seem to become less pronounced with age.

Gametes of the two *Fucus* species used in this study are continually differentiated and the older, more mature gametes are periodically released twice per day in the normal tidal cycle. Since stored plants were not subject to this tidal action the population of gametes experimentally released from stored plants will contain a relatively higher proportion of older eggs.

Specificity in seaweed fertilisation, as in sea-urchin[13] and mammalian[14] fertilisation is probably based on surface-localised complementary macromolecular recognition phenomena. It is tentatively suggested, therefore, that the partial breakdown of an inherent sterility barrier in the interspecific crosses is due to modification in the properties of the appropriate membrane receptors of the older egg cells. The molecular nature of these receptors is being investigated now. But, until more is known about the effects of external factors on the biochemistry of gamete development and the resulting implications on fertilisation, speculation on the ecological significance of the reduced specificity would be premature.

Hedgehogs use toad venom in their own defence

I REPORT here that toxic secretions evolved in prey organisms such as toads (*Bufo*) as chemical anti-predator mechanisms are used by hedgehogs (Insectivora, Erinaceidae) to enhance their own mechanical anti-predator adaptations—the spines, modified hairs, of the back. The secretions are taken into the mouth and licked on to the spines. In spite of interest in chemical, mechanical and behavioural anti-predator adaptions of both invertebrates and vertebrates[1] there have been no reports of the behavioural utilisation of the anti-predator secretions of one species by another for its own defence. Toad skin is one of many irritating substances used by hedgehogs in self-anointing, and the presence of any of these, fresh or dried, on the spines would probably increase the pain or potential of infection to the would-be predator.

The survival value of spines is enhanced by the hedgehog rolling into a ball or 'boxing' when contacted or approached by a predator. Boxing consists of erecting the spines over the head and lunging into the approaching predator. Hedgehogs also display a curious behaviour pattern known as *Selbstbespeicheln* or self-annointing. Published reports[2–4] and my observations on 18 *Atelerix pruneri* and one *Hemiechinus auritus* agree that this behaviour involves frothing at the mouth then spreading the froth with the tongue on to the spines. Many possible functions of this behaviour have been considered and rejected[2].

Substances which naturally release self-annointing behaviour are either novel or noxious (irritating to mucosal membranes). Other common releasers are tobacco, soap and salamander skin secretions. Toad skin has often been mentioned as a releaser. Because toads (*Bufo*) occur throughout the natural range of hedgehogs, are commonly eaten by hedgehogs[5] and produce toxins in the granular glands of the skin it is possible that hedgehogs use *Bufo* skin toxin in their own defence.

Each time a toad (50+ times) with skin intact was contacted by adult or laboratory-reared juvenile hedgehogs they displayed self-annointing behaviour. When the following species of *Bufo* were offered to hedgehogs, the results were identical: *B. alvarius, B. americanus, B. boreas, B. marinus, B. quercicus, B. regularis, B. terrestris* and *B. woodhousei.* Toad skin, fresh (six trials) or dried (six trials), or excised toad paratoid glands (15 trials) always elicited self-annointing, but toads with the skin removed (six trials) were always eaten without self-annointing. Bullfrogs, *Rana catesbeiana,* and white mice (at least 30 each) were eaten without self-anointing. When hedgehogs attack toads they first bite and chew the paratoid glands (these contain the greatest concentration of skin toxins) then distribute the resultant frothy mixture of toad skin secretion and saliva over the spines (Fig. 1); the toad is then often eaten. In two cases *Hemiechinus* grasped the toad in its mouth and rubbed the skin over its spines (Fig. 2).

Observations of six *Atelerix* born and raised in captivity indicate that the self-anointing (Fig. 3) and other anti-predator behaviour are expressed before the eyes open at age 18–24 d. Long white spines are emergent within minutes after birth and a second stiffer set of dark spines emerges within 2–4 d. From 6 to 10 d after birth the young begin boxing behaviour, orienting the body towards any contact, and hissing. They can roll into a full ball by 2 weeks. Self-annointing is fully developed at 15–16 d (13-d-old juveniles do not exhibit this behaviour) in response to various stimuli such as sour milk, hands freshly washed with soap, or tobacco juice. These juveniles also licked substances from their mother's spines and applied them to their own spines.

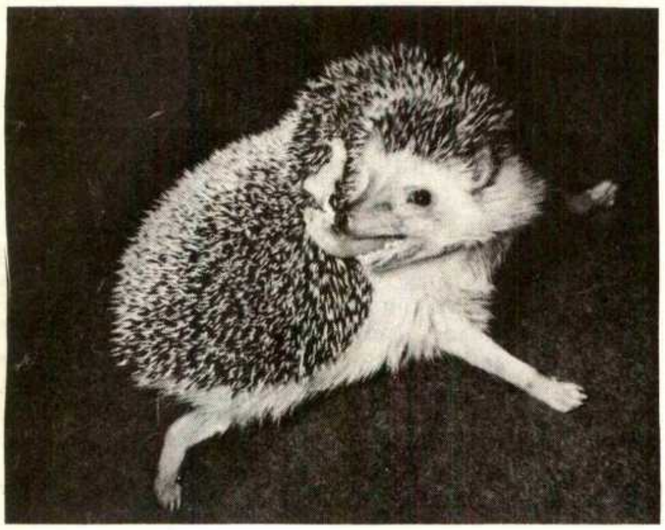

Fig. 1 Adult *Atelerix* self-annointing after chewing a toad (*Bufo*). The forth of saliva and toad skin secretion is being applied to the spines with the tongue.

To determine whether self-annointing with toad skin secretion would increase the pain inflicted by penetration of a hedgehog spine, spines were removed from an *Atelerix* and jabbed into the inner forearm of the author and six volunteers. Each subject jabbed himself with four spines in random order (only the author knew the order). The spines were treated as follows: (1) spines washed in alcohol; (2) spines washed then coated with hedgehog saliva; (3) spines washed then coated directly with *Bufo marinus* skin secretion; (4) spines freshly self-annointed with *Bufo marinus* skin secretion. In only one of seven cases did spines of groups (1) or (2) cause any reddening, and there was no pain or burning other than the mechanical pain of puncture. In group (3) six of seven subjects and in group (4) all subjects experienced immediate intense local burning. Splotchy red areas 8–46 mm ($\bar{x} = 24.6$ mm) developed around the puncture and reached their greatest development in 10–40 min ($\bar{x} = 18.1$ min). Burning lasted for 5–60 min and varied greatly in intensity. The reaction to two self-annointed spines dried for 1 week was the same as to freshly self-annointed spines.

Self-annointing behaviour is not only widespread among hedgehogs, having been reported in *Erinaceus, Aethechinus, Paraechinus, Hemiechinus* and *Atelerix*[2], but has also been described in the hedgehog tenrec *Echinops*[6], an insectivore of the family Tenrecidae convergent with the true hedgehogs in the presence of spines. Tenrecs, in contrast to hedgehogs, wipe the mixture of stimulating substance and saliva over the spines with the forepaws. In hedgehogs the mixture is always licked directly on to the spines, never on to the forepaws. These stereotyped behaviour patterns of both hedgehogs and tenrecs are released by chemical stimuli perceived by taste or smell, involve increased salivation, and include the spreading of this saliva–substance mixture on to the spines. The behavioural components of self-annointing in the two families of insectivores are quite different and were apparently developed independently[6]. The presence of these different behaviour patterns which both utilise saliva as a vehicle for the application of irritating substances on to spines suggests that these behaviours increase fitness. The fact that the anti-predator behaviour patterns including self-annointing are innate and fully developed in hedgehogs before leaving the nest further supports their importance.

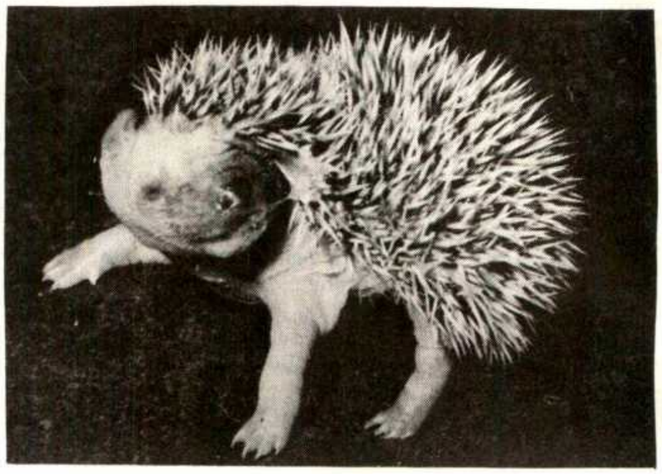

Fig. 3 Seventeen-day-old juvenile *Atelerix* frothing at the mouth and self-annointing after licking tobacco juice. The eyes have not yet opened.

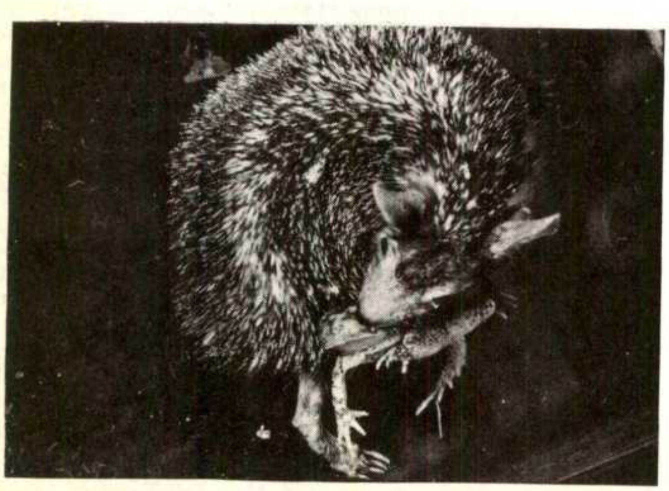
Fig. 2 *Hemiechinus* rubbing *Bufo* against spines. Froth is visible on spines along the side and between the ears.



I thank J. A. Johnson and the graduate students who loaned me their arms for help. Some of this work was supported by a research fellowship from the E. N. Huyck Preserve, Rensselaerville, New York.

Diets of early Miocene African hominoids

MOST reviewers of East African early Miocene apes have been impressed by their similarity, as an adaptive array, to living Cebidae. These apes are most frequently pictured as small to medium-sized cebid-like quadrupeds occupying arboreal[1-6], fruit- and leaf-eating[3,7,8], tropical rainforest[9] niches. It has also been suggested that the decline in the diversity of apes in middle to late Miocene times was triggered by ecological competition from rapidly radiating cercopithecids[9-11]. In this report

I examine the molar structure of early Miocene hominoids to see whether or not these species occupied a wide spectrum of fruit- and leaf-eating niches, similar to those of today's cercopithecids.

I have analysed 65 specimens of extant pongids and hylobatids from the Museè Royal de l'Afrique Centrale, the American Museum of Natural History and the US National Museum of Natural History. The sample includes 10 of the 11 recognised ape species[12]. The early Miocene fossil apes come from the collections of the Kenya National Museum and the British Museum of Natural History. Three species of New World monkeys were also examined. Twelve previously described dimensions[13] of unworn lower second molars were estimated: The mesiodistal M_2 length, used as an estimate of overall size; the heights of the metaconid and hypoconid; the lengths of shearing blades 1–8; and the summed surface areas of the trigonid and talonid basins. Cusp heights are interpreted as reflecting capacity for resistance to dental wear; shearing blade lengths and total basin areas reflect the relative importance of shearing, crushing and grinding in mastication. To eliminate the effects of allometry on these variables, I selected different-sized species with diets composed primarily of fruit (two *Pan* and five *Hylobates* species). For this group, 11 regression lines for the $\log_e$ of the molar dimensions (with $\log_e$ length as the independent variable) were fitted by the least squares method. The distance each species' molar dimensions falls above or below the *Pan-Hylobates* regression was expressed as a percentage of the expected dimensions for that tooth length[14]. The percentage values derived from each of the 11 regressions were used to produce a correlation matrix from which principal components were extracted. The resulting factor loadings (Table 1) were used to produce principal-component values for each specimen studied. The mean principal-component value for each species is shown in Fig. 1. Student's *t* tests were used to assess the significance of differences between the species means on each component axis. The factor loadings derived from this analysis also were used to produce principal-components values for specimens of living ceboids, Old World monkeys and fossil hominoids. The species means for these forms are shown in Fig. 1. In another principal components analysis, all living and fossil species were run together. The resultant factor loadings and principal-component values were extremely similar and are not reported.

Table 1 Factor loadings for the first two principal components of the analysis of *Z*-score corrected, % difference data of the lower second molars of 11 extant apes

Variable	Factor loadings Component 1 (50% of variance)	Component 2 (17.7% of variance)
M_2 hypoconid height	0.878	−0.034
M_2 metaconid height	0.596	0.339
M_2 shearing blade 1	0.363	0.484
2	−0.891	0.102
3	0.277	0.703
4	−0.674	0.500
5	0.767	0.438
6	0.587	−0.587
7n	−0.759	0.494
8	−0.780	−0.052
Total crushing area (9,10 n, x)	0.940	0.248

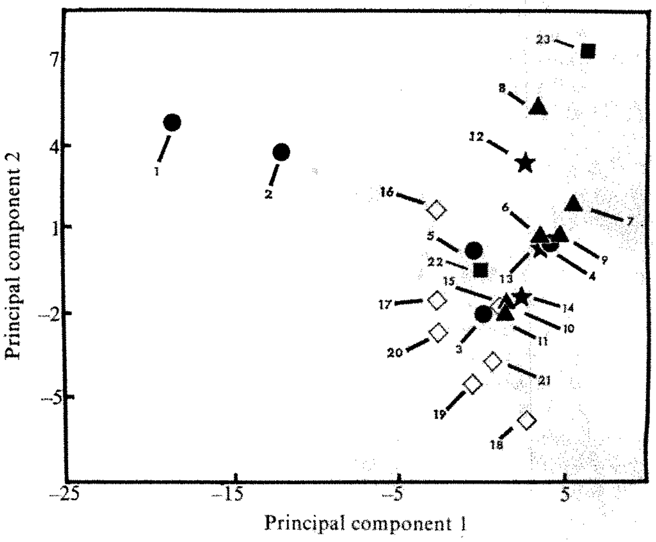

Fig. 1 Plot of principal components scores of primate M_2s along the first two principal components axes. Sample sizes are included in parentheses. Extant Pongidae (●): 1, *Gorilla gorilla beringei* (8); 2, *Gorilla gorilla gorilla* (6); 3, *Pan troglodytes* (10); 4, *Pan paniscus* (11); 5, *Pongo pygmaeus* (5). Extant Hylobatidae (▲): 6, *Hylobates lar* (5); 7, *Hylobates hoolock* (2); 8, *Symphalangus syndactylus* (3); 9, *Hylobates moloch* (5); 10, *Hylobates klossi* (5); 11, *H. agilis*. Cebidae (★): 12, *Aloutta seniculus* (5); 13, *Ateles belzelbuth* (5); 14, *Cebus capucinus* (5). Extinct Hominoidea (◇): 15-17 Songhor; 15, '*Limnopithecus*' *legetet* (3); 16, *Dryopithecus gordoni* (6), 17, *Dryopithecus maor* (3). 18–21, Rusinga Island; 18, '*Limnopithecus*' *legetet* (2); 19, *Dryopithecus africanus* (5); 20, *Dryopithecus nyanzae* (7); 21, '*L.*' *macinnesi* (8). Cercopithecidae (■): 22, *Cercocebus albigena* (6); 23, *Colobus badius* (6).

The primarily folivorous species, *Gorilla*[15] and *Symphalangus*[16] are clearly separated morphologically from other, more frugivorous, pongid and hylobatid species[17–9] on the first and second principal component axes which account for 67.7% of the total variance of the system (Fig. 1). The first principal component separates *Gorilla gorilla* from all other species by a combination of high cusps, enlarged crushing basins and elongate molar crests 5 and 6 (Table 1). But, the first principal component does not separate folivorous from frugivorous hylobatids. The second principal component separates folivorous from frugivorous species. The former have relatively high metaconids and a great overall amount of shearing and crushing (Table 1). The mean second principal-component values of *Gorilla gorilla* subspecies and *Symphalangus syndactylus* are significantly larger (at the 95% confidence level) than those of all other pongid and hylobatid species tested. This result conforms with the diet–molar morphology correlation seen in other mammalian groups. Folivorous species of Old World monkeys and phalangeroid marsupials also have better developed shearing blades than frugivorous species[20]. Leaves, bark, buds and other folivorous materials tend to contain large amounts of structural carbohydrates (cellulose, hemicellulose) which require thorough trituration facilitated by well developed molar structures, to enhance digestibility[20]. In contrast, fruits tend to be lower in structural carbohydrates and higher in soluble carbohydrates which are highly digestible even without full trituration[21].

Before using this principal components analysis as a model for comparisons of Miocene species, its reliability as a predictor of dietary habits was tested for representative folivorous and frugivorous Old and New World monkeys. To do this, *Z*-standardised percentage scores were tabulated from the *Pan–Hylobates* regressions for the highly frugivorous New World species *Ateles* and *Cebus*[22] and the folivore *Alouatta*[22,23]. These species' values are interpolated into Fig. 1. *Ateles* and *Cebus* fall with the frugivorous hylobatids and pongids on the second principal component and have significantly smaller (at the 95% confidence level) second-component values than do the folivorous hominoids. The second principal-component value for *Alouatta* is significantly larger than all frugivorous ceboids and hominoids analysed, and is not significantly different from the more folivorous *Symphalangus* or *Gorilla* species. Apparently, the morphological distinctions between fruit- and leaf-eating cebids are analogous to those seen between fruit- and leaf-eating hominoids. Also interpolated into Fig. 1 are the principal-component values for two species of cercopithecoid monkey, *Cercocebus albigena* and *Colobus badius*. The former is primarily a fruit eater whereas the latter eats primarily leaves. *Cercocebus* falls with primarily fruit-eating hominoids and cebids, whereas *Colobus* falls with the leaf-eating species of these groups. It may be concluded from the above that second lower molar morphology can be used to reliably separate extant fruit-eating from leaf-eating Higher Primates.

Lower second molars of fossil apes from two East African Miocene sites, Songhor and Rusinga Island, spanning the time period of 18–20 myr BP (ref. 24) were measured. The material included specimens of six of the seven species known from these sites[9]: *Dryopithecus gordoni*, *D. major*, *D. nyanzae*, *D. africanus*, '*Limnopithecus*' *macinnesi* and '*L.*' *legetet*. The lower dentition of *D. vancouveringi* is not yet known (identified). As with the Old and New World monkeys reported above, *Z*-standardised percentage scores were calculated from the *Pan–Hylobates* regressions, principal-component values were calculated for individual specimens and the species, mean was determined for each species grouped by locality. The species' values are plotted in Fig. 1. The Songhor specimens of *D. major*, and '*L.*' *legetet* fall with living frugivorous hylobatids on the second principal component, and are very close to *Pan troglodytes* as well. Both the fossil species have significantly smaller second-component values than extant folivorous species at the 95% confidence level. A frugivorous diet for these species is indicated. *Dryopithecus gordoni* falls between the ranges of living frugivores and folivores on the second principal component axis. This species is not significantly different from either *Gorilla gorilla gorilla* or from several of the species of *Hylobates*. Rusinga Island specimens of *D. nyanzae*, *D. Africanus*, '*L.*' *legetet* and '*L.*' *macinnesi* fall with frugivorous extant hominoids and have significantly smaller second-component values than extant folivorous species. Points 15 and 18 in Fig. 1 representing '*L.*' *legetet* from two different sites are not significantly different from one another at the 95% confidence level. This analysis strongly indicates that the known early Miocene hominoids (with the possible exception of *D. gordoni*) probably had diets consisting largely of fruit. In this respect they show less dietary diversity than the pongids of hylobatids of today, since members of both those groups have folivorous representatives. Judging from the molar morphology *D. major* has no apparent dietary affinity with *Gorilla*, contrary to previous suggestions[8].

Early Miocene apes apparently were quite similar, adaptively, to some extant cercopithecines and a case can be made that monkeys replaced apes in middle to late Miocene times. Early apes have been collected at sites which sample tropical rain-forest environments[9] where cercopithecines are abundant today, in terms of species numbers. Early apes had far greater species diversity than the apes of today and in this respect they mirror the diversity of living forest-dwelling cercopithecines[9]. Dental dimensions suggest that early apes and living forest dwelling cercopithecines have a similar body size range (2–40 kg). Most of the early Miocene apes are similar to extant cercopithecines in being arboreal quadrupeds[1-6] with some of the larger forms being at least partially terrestrial[7]. Finally, early Miocene apes were primarily frugivorous, as is the case with many arboreal cercopithecines of today.

But these similarities should not be taken as demonstrating an identity in the adaptive zones of early Miocene apes and extant forest monkeys. There is no evidence that any early Miocene hominoids fed on seasonally high proportions of leaves, bark, buds, or grasses, as do some cercopithecines today. There were no colobine vicars among the early Miocene hominoids. Thus, in addition to displacing early hominoids, the cercopithecid adaptive radiation may also have come at the expense of other arboreal and semiterrestrial species. Possibly the African colobine leaf-eating radiation displaced some hyracoids, anomalurid rodents or arboreal reptiles, some of which eat bark and leaves[25,26].

I thank R. Leakey, P. Andrews, R. Thorington, S. Anderson and T. Van Den Audenaerde for permission to study materials in their care, and J. Fleagle, E. Delson, G. Conroy, M. Cartmill, K. Brown and D. R. Pilbeam for thoughtful criticisms. This research was supported by NSF grant GS-43262.

Further study of an auditory illusion

DEUTSCH[1] reported an interesting auditory illusion when different tones are presented to the two ears. She used chords alternating every 250 ms between 400 Hz to the left ear, 800 Hz to the right and 800 Hz to the left, 400 Hz to the right. Subjects never heard the correct pattern; they perceived most often a low tone in one ear alternating with a high tone in the other. Right-handed subjects tended to hear the high tone in the right ear and the low tone in the left ear, but left-handed subjects showed no such tendency. Deutsch and Roll later found that right-handed subjects tended to report the sequence delivered to the right ear rather than that to the left, but the tone reported tended to be localised in the ear receiving the higher frequency[2]. They concluded that there were separate mechanisms for perceiving location and pitch, and that the right ear preference for pitch was related to cerebral dominance. Efron and Yund[3,4] reported a related phenomenon using a sequence of two pairs of tones : 1,500 Hz to the right ear, 1,900 Hz to the left followed by 1,900 Hz to the right ear, 1,500 Hz to the left. Again most subjects heard a single note each time. Efron and Yund systematically varied the relative intensity of the two tones and found that the location of the perceived sound depended critically on this variation, always being heard towards the side receiving the more intense sound. If the two intensities were exactly balanced for an individual, then the perceived sound was subjectively located in the midline. The subjective pitch of the sound heard was a separate function from its location, and frequently the pitch of the less intense sound was heard, but localised in the ear receiving the more intense sound. We have used Deutsch's frequencies of 400 Hz and 800 Hz, and also 457 Hz and 857 Hz. We presented two consecutive pairs of tones, systematically varying the intensity, and confirmed Efron and Yund's results. Using equal intensities we obtained different results from Deutsch.

The tones lasted 250 ms, with a rise and fall time of about 10 ms, and were presented at an intensity of 65 decibels 2×10^{-5} N m^{-2} through TDH-39 earphones.

Twenty-four right-handed subjects, without extensive musical training, were tested with an audiometer at the two frequencies used and any small difference in acuity was approximately balanced by adjusting the intensity of the tones. Subjects were first given each tone separately as standards of high and low, and then were allowed to listen to the pair of chords as often as they wished by pushing a button to obtain a presentation. For each pair of chords they were asked to indicate on a response sheet exactly what they heard in terms of pitch and location. Each subject received eight stimulus configurations; on two of these the tone of higher frequency was attenuated by 10 dB and on another two the lower tone was attenuated by 10 dB.

A second experiment on another 24 subjects was identical, except that frequencies of 457 Hz and 857 Hz were used, to see if there was any difference with tones lacking a simple harmonic relation.

The results relating to the relative intensity of the two tones are clear. In both experiments, when one of the tones was attenuated by 10 dB, then if only one tone was perceived it was located in the ear receiving the higher intensity on 85% of cases. The pitch of the tone heard was not necessarily that of the more intense tone. This confirms the results of Efron and Yund, that the location of the perceived sound depends on the relative effective intensity of the tones for each individual subject. It also suggests that Deutsch's finding that the high tone tends to be localised in the right ear and the low tone in the left may be due to small intensity differences, or to differences in acuity between the ears of individual subjects.

What subjects hear, as opposed to where they hear it, is a more complex function. Table 1 shows a summary of the results when the two tones are of approximately equal intensity. For each chord (High-L, Low-R or High-R, Low-L) is shown the number of times it was heard as a chord, or single high, low or medium note, irrespective of location. Each of the twenty-four subjects made four observations of each chord. Order effects were not significant.

Table 1 Number of times each chord was heard as a chord, or single high, low or medium pitched note

Stimulus frequencies	400 Hz/800 Hz		457 Hz/857 Hz	
Stimulus chord	High–L Low–R	High–R Low–L	High–L Low–R	High–R Low–L
Heard as:				
Chord	0	0	30	33
High	42	40	40	27
Medium	22	28	9	3
Low	32	28	17	33

L, left; R, right.

The perception of a single note is very clear using frequencies of 400 Hz and 800 Hz; a single note was heard on all occasions. With frequencies of 457 Hz and 857 Hz a single note was reported about 66% of the time—but nearly half the subjects heard a chord on some occasion. The illusion seems very strong if the notes have a simple harmonic relation and less strong, but still common, if they do not.

No overall pattern emerges from the detail of what is heard when only one note is reported, but Deutsch's result that the right ear determines what is heard is not confirmed. Whether the notes have a simple harmonic relationship or not, the stimulus configuration does not significantly influence the pitch of the reported note. The function determining what is heard is complex, and shows considerable individual differences. Individual subjects tend to be fairly consistent in their preferences.

The illusion falls into the class of 'curious binaural phenomena' reviewed by Tobias[5], who concluded that 'any similarity between two sounds may lead to their fusion, if the similar factors fall below 1,500 Hz and come close to coinciding in time'.

Racial differences in the frequency of Q and C chromosomal heteromorphisms

THE biological and clinical implications of human chromosome heteromorphisms are poorly understood. These heteromorphisms are limited to certain groups, and are heritable[1]. Consistent variability between people, in both size and staining properties, is observed. This may reflect either structural or biochemical variations. Before chromosome banding procedures, the length of the Y was known to vary from person to person and from one ethnic group to another[2]. Some autosomal regions were also found to differ in various racial groups[3,4]. Using Q- and C-banding procedures, we have regions scored were (1) on the long arms (*qh*) of chromosomes 1, 9 and 16; (2) on the short arms (*p*) of the acrocentric autosomes (13–15 and 21–22); and (3) on the centromere (*c*) of all other chromosomes. The results indicate significant differences between the samples of black and white children.

Chromosome studies of peripheral blood lymphocytes were originally done on 4,342, 7–8-yr-old, children from the Collaborative Perinatal Study through the collaboration of cytogenetic laboratories in five cities. The culture and harvest methods are described elsewhere[5]. Most of the data presented here, however, were obtained from a subsample of 415 children. This was derived, using random numbers, from the larger study group and designed to give equal numbers of children of each race above and below an IQ of 85 (ref. 6). Slides from these children were sent to the coordinating centre for Q-banding. The same slides from 200 of the 415 children were also successfully C-banded. In all cases, 5–10 cells were photographed and analysed; two karyotypes were prepared. If C-banding was done, two dual karyotypes with Q- and C-banded chromosomes were prepared from the same cells. It is important to note that the C-banding of all chromosomes could be studied because each chromosome was preidentified by Q-banding. Without this sequential staining, only 1, 9, 16 and Y can be studied.

Heteromorphisms were scored according to predetermined criteria without knowledge of race, IQ or other parameters. For Q-banding, the five intensity levels established in 1971 at the Paris Conference were used[7]. The levels are brilliant, intense, medium, pale and negative; for convenience, they are referred to as levels 5–1, respectively. For C-band heteromorphisms, the karyotype was arranged by decreasing size of the C-band region from largest to smallest[8]. This permitted comparison of C-band regions on homologous and nonhomologous chromosomes having similar sized heteromorphisms. Classification of both Q- and C-band heteromorphisms was done by two independent observers, whose scores were virtually identical.

There were 190 black and 194 white children: 98 of the black and 52 of the white children had an IQ less than 85 and the remaining children (92 black and 142 white) had an IQ of 85 or above.

Before scoring the heteromorphisms, each set of slides was scored for quality of culture and quality of banding. There were no significant differences in these distributions between races or between IQ groups. In all groups, the number of heteromorphisms detected directly reflected the quality of the culture. On the average 3.3 Q- and 3.9 C-band heteromorphisms per child were found.

The frequencies of Q-band heteromorphisms in the two racial groups are given in Table 1. An average of seven heteromorphisms was present in black children and an average of five in white. Where there were significant racial Q-band differences, blacks tended to brilliant or intense heteromorphisms on chromosomes 3, 13 and 22. Chromosome 4 was the single exception. Even when the difference was not statistically significant, the frequency of level 4 and 5 heteromorphism tended to be greater in blacks. We conclude that bright Q-band heteromorphisms are generally more common in blacks.

The centromere (C-band) heteromorphisms were studied in 95 white and 97 black children. These were much less frequent than the prominent Q-band heteromorphisms or *qh* heteromorphisms in 1, 9 and 16. Therefore, data for all chromosomes were pooled. In the white children, the number with small ($N = 44$) and large ($N = 44$) C-band regions was equal, whereas 50 black children had small and 78 had large heteromorphic regions. Overall, larger than usual C-band regions were clearly more common in blacks ($P < 0.005$). Most of this difference was due to chromosomes 4, 18 and 19. No individuals in the white sample had prominent, large centromere heteromorphic regions for chromosomes 4, 18 and 19, but 7–9% of the black children had large centromere regions for these chromosomes. Five white children had a large centromeric C region in an X chromosome in contrast to only one black child.

Table 1 Frequencies of Q-banding heteromorphisms in white and black ethnic groups

Chromosome region	Level (s)	White ($N = 205$) *N*	White ($N = 205$) Prop.*	Black ($N = 210$) *N*	Black ($N = 210$) Prop.*	*P* value
3*c*	4	57	0.28	89	$\underline{0.42}$	< 0.01
	5	119	0.58	119	0.57	ns†
4*c*	4,5	42	$\underline{0.20}$	20	0.09	< 0.01
13*p*	4	87	0.42	113	$\underline{0.54}$	< 0.01
	5	22	0.11	70	$\underline{0.33}$	< 0.001
13*s*	4,5	9	0.04	20	$\underline{0.10}$	< 0.01
14*s*	4,5	23	0.11	27	0.13	ns
15*p*	4,5	2	0.01	6	0.03	ns
15*s*	4,5	21	0.10	21	0.10	ns
21*p*	4,5	1	0.005	4	0.02	ns
21*s*	4,5	16	0.08	28	0.13	ns
22*p*	4,5	4	0.02	8	0.04	ns
22*s*	4,5	12	0.06	29	$\underline{0.14}$	< 0.01

*Proportion of people, either heterozygous or homozygous. Significantly higher frequencies are underlined.

†ns, not significant χ^2 value.

The prominent C-band regions on chromosomes 1, 9 and 16 were also studied. These heterochromatic (*h*) regions are usually on the long (*q*) arm of these chromosomes just below the centromere and are termed *qh* regions. There were no obvious racial differences in either extremely small or large *h* regions for chromosomes 1, 9 or 16. Because of greater complexity of these data, they were analysed on a per chromosome basis, rather than a per person basis and will be reported separately by us. Occasionally, however, they seem to be inverted and to be partially or wholly on the short arm of these chromosomes. Although there is no information which permits us to determine whether these are true inversions or whether they represent unusually placed centromeres, the term 'inversion' has been used for a decade and remains reasonably descriptive. Partial inversions were scored when there was a dumbell-shaped C-region, with the centromeric constriction near the centre of the dark-staining C-band regions. Complete inversions were those in which all of the C-band positive material was found on the short arm. These heteromorphisms were analysed in the overall sample of 4,342 children since they can be reasonably well detected in G-banded and unbanded cells (Table 2).

Table 2 Frequencies of 1 and 9 *q* inversions* in white and black ethnic groups in the overall sample

Inversions	White ($N = 3084$) *N*	White ($N = 3084$) %	Black ($N = 1780$) *N*	Black ($N = 1780$) %	*P* value
1 *h* partial	14	0.45	1	0.06	< 0.05
9 *h* partial	17	0.55	8	0.45	ns
9 *h* complete	4	0.13	19	1.07	< 0.001

*'Partial inversions' were defined as those in which the centromere was in the middle of the *h* region and 'complete inversions' of chromosome 9 as those in which there was a metacentric 9 with the entire *h* region being in the short arm.

Complete inversion of the 9*qh* region was much (six times) more common in blacks, as had been reported before banding[4]. Conversely, partial inversions of chromosome 1 were much more common (eight times) in whites. No complete inversions of chromosome 1 and no inversions, even partial, of the C-band region on chromosome 16 were observed in our sample, suggesting that these inversions are uncommon in both racial groups.

Previously published population surveys using banding techniques have dealt solely with white populations[8–13]. Only in the present survey, therefore, can the possibility of racial differences be studied. There was clearly a significant black/white difference in the frequency of Q- and C-band chromosome heteromorphisms, with blacks generally having more prominent heteromorphisms than whites. Presumably this reflects a greater degree of redundancy of certain classes of human satellite DNA in these regions. Studies with annealing techniques have not yet been carried out in individuals of different racial or ethnic backgrounds. As with ethnic differences in blood groups, enzyme types and other single gene markers, the evolutionary significance of these frequency differences is purely conjectural. They are clearly of similar genetic and anthropological interest, however, and may be of value in planning linkage and population research.

Androgenetic origin of hydatidiform mole

CLASSIC hydatidiform mole is the product of an abnormal pregnancy with grossly swollen chorionic villi, but without an embryo, cord or amniotic membrane. Histologically, the villi are characterised by advanced hyperplasia and anaplasia of the trophoblast, oedema of the stroma and the absence of foetal capillaries[1]. A malignant change to invasive mole or choriocarcinoma is frequent. The karyotype of the mole is predominantly, if not exclusively, 46,XX. We have made a cytogenetic study of the origin of hydatidiform mole and found that it receives only paternal chromosomes and is therefore androgenetic in origin.

Karyotyping was done on 20 moles: in 13 cases on uncultured villi, in three cases on cultured villi and in the other four cases on both cultured and uncultured villi. Ten moles were of Caucasian origin and ten were of Japanese origin. All had a 46,XX karyotype.

The mode of inheritance of molar chromosomes was studied using fluorescence Q and R-band polymorphisms as markers, as described before[2]. Seven moles, two Spanish and five Japanese in origin, and the parents were studied (Table 1). Chromosome slide preparations were made from both cultured and uncultured villi of molar specimens, and from short term lymphocyte cultures of the parents. Seven pairs of chromosomes (nos 3, 4, 13, 14, 15, 21 and 22) from each of the seven moles were scored for fluorescence banding polymorphisms (Table 1). In all of the 49 pairs scored, homologous chromosomes were homozygous for banding polymorphisms (Fig. 1). In 26 pairs of chromosomes, neither of the maternal homologues was transmitted to the mole. In 20 of the 26 pairs, a paternal chromosome could be shown to be inherited in duplicate by the mole (Fig. 2). Comparison of the paternal and molar chromosomes revealed that in 30 pairs the paternal homologues were heterozygous for banding polymorphisms, while those of the moles were homozygous (Table 2).

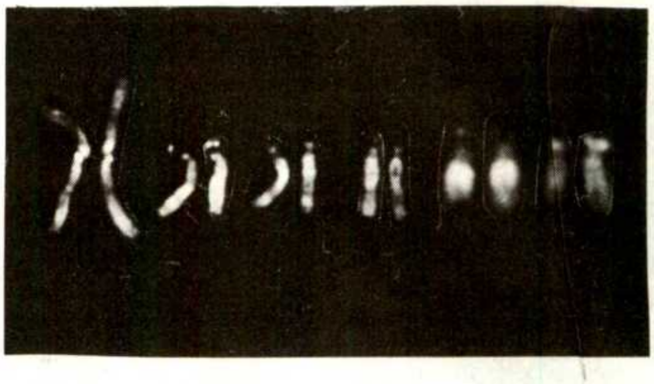

Fig. 1 Q-banded direct chromosome preparation from case 2. All the homologous chromosomes are homozygous for banding polymorphisms.

Stromal cells in villi were studied for the X chromatin in 47 moles, 18 Caucasian and 29 Japanese in origin. All but three were X-chromatin positive, varying in frequency between 73% and 85.5%. Of the three X-chromatin negative moles, two were Y-chromatin negative, while the remaining one was Y-chromatin positive in 54% of its stromal cells. Necrotic changes could be excluded as a cause for the latter findings. Karyotyping was not successful in the three X-chromatin negative moles.

A total of 35 couples each with a molar pregnancy were karyotyped, and two of the women had a balanced reciprocal translocation: t(7;8)(q22;p21) and t(3;22)(p11;p11). The mole from the first translocation carrier woman revealed a 46,XX karyotype, while that from the latter failed to yield a karyotype.

Our results indicate that moles are androgenetic in origin. Androgenesis is the development of an ovum under the influence of a spermatozoan nucleus, the egg nucleus being either absent or inactivated[3]. Androgenetic 'zygoids' are usually haploid. Diploid androgenesis, as in these moles, involves a male chromosome complement that has become diploid through fertilisation by two sperm (dispermy), by a diploid sperm or by a haploid sperm followed by duplication of its chromosomes. In the case of dispermy, however, there would be an equal number of heterozygous and homozygous chromosome pairs. The fact that all 30 informative chromosome pairs in the moles studied were homozygous essentially rules out this possibility. The chromosome findings are compatible with either fertilisation by a diploid sperm due to nondivision at second meiotic division or fertilisation by a haploid sperm followed by duplication of its chromosomes and nondivision at first 'blastomere' mitosis. These two possibilities are indistinguishable by the method we used. Both these events would produce a diploid zygoid containing either XX or YY sex chromosomes. Because

Table 1 Mode of inheritance of polymorphic chromosomes in hydatidiform moles

P, paternal; HM, hydatidiform mole; a and b do not represent two specific phenotypes, they are merely symbols.

a cell must have at least one X chromosome to survive, presumably only the XX 'zygoids' could survive to become moles.

The X-chromatin negative moles in our study may have had two X chromosomes with neither X inactivated. Alternatively, they may have arisen through a mechanism different from that in the seven moles of which the chromosome source has been studied. Abnormal first meiotic division in the male, for example, would result in XY diploid sperm, which in turn could produce XY moles. The X-chromatin negative, Y-chromatin positive mole in this study may have arisen by this mechanism.

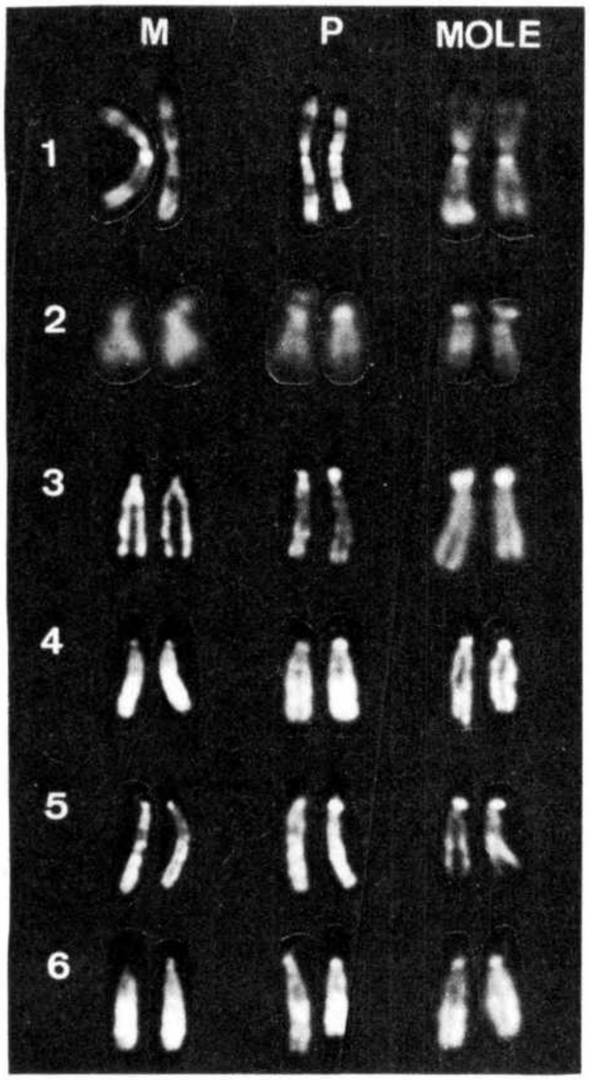

Fig. 2 Chromosomal polymorphisms demonstrating the differences between the maternal (M), paternal (P) and molar (mole) chromosomes. Cases 1, 2, 4, 5 and 6: Q-banding. Case 3: R-banding. Case 1: no. 3. Case 2: no. 22. Case 3: no. 14. Cases 4–6: no. 13. In each case, a paternal chromosome (right) was transmitted in duplicate to the mole, while neither of the maternal homologues was inherited by the mole.

The finding of two translocation carrier women among the 35 couples with molar pregnancies is interesting. Their frequency of 6% among the women studied is higher than that of 0.3% in the general adult population[4]. The presence of translocation chromosomes may interfere with female meiosis and encourage the production of ova with absent or inactivated nuclei.

The high malignancy rate in hydatidiform mole could be explained by a recessive mutation of a gene (or genes) which controls cell growth. Because the homologous chromosomes in the mole are genetically homozygous except for the genes exchanged through crossover, they are also homozygous for the mutation and thus may escape from normal growth control.

Wide geographic variations have been known in the frequency of moles, which are more frequent in Asian countries[5] as well as Latin American countries of the tropical zone[6] than European and North American countries. The results reported here indicate that the Asian disease is the same as that found among the Caucasians. This finding, however, fails to explain why its incidence is higher among Orientals. Study of the frequency of diploid sperm among Oriental males and that of defective ova among Oriental females could shed light on this question.

We thank Drs N. Niikawa and T. Kusumi, and Mrs E. Merotto for technical assistance. This work was supported by grants from the World Health Organization, the Ford Foundation Population Programme and the Swiss National Foundation.

Genetic model for observed distributions of proportions of haemoglobin in sickle-cell trait

IN individuals with sickle-cell trait, mature erythrocytes contain less haemoglobin (Hb) S than HbA. Although variations in the proportions of HbS and HbA have been recognised since quantification of the Hb fractions first became possible, the mechanisms responsible are incompletely understood. Nutritional deficiencies[1,2] and other non-genetic conditions[3,4] affecting globin synthesis may alter these proportions in individual heterozygotes but are unlikely to explain the variations found in population surveys. A simple genetic model which can account for the observed distributions of the proportions of HbS in sickle cell trait is presented here.

For most populations, the observed proportions of HbS in heterozygotes may be grouped into three phenotypic classes with mean values of 25% (range 20–29%), 33% (range 30–36%), and 40% (range 37–50%). The model assumes that these values are determined by two types of genetic units (explained below), G_1 and G_2, such that the phenotypes with 25, 33 and 40% of HbS correspond to the G_1G_1, G_1G_2 and G_2G_2 genotypes. If the respective frequencies of G_1 and G_2 are p_1 and p_2 then for a population in Hardy–Weinberg equilibrium, the genotype frequencies are given by the binomial expansion $(p_1+p_2)^2$ as shown in Table 1. Given the number of individuals observed in each phenotypic class, the gene frequencies p_1 and p_2, and the number of individuals expected in each class may be calculated[5]. The goodness of fit of these expected frequencies with observed phenotype frequencies may be evaluated with the χ^2 test[5].

Table 1 Phenotypes and genotypes: model with two genetic units (G_1 and G_2)

Phenotype (% HbS) Mean	Range	Model genotype	Frequencies
25	(20–29)	G_1G_1	p_1^2
33	(30–36)	G_1G_2	$2p_1p_2$
40	(37–50)	G_2G_2	p_2^2

Ten studies (refs 6–14 and G. Brittenham *et al.*, unpublished) have described the distributions of the proportions of HbS in 13 populations. Table 2 displays the observed and expected numbers of individuals in each of the phenotypic classes, the calculated gene frequencies for G_1 and G_2, p_1 and p_2, and χ^2 values derived from the data contained in these reports. Since these studies have used different methods of quantifying the Hb fractions, the range of the phenotypic classes varies slightly by study. The results show an excellent fit between these observations and the predictions of the model; none differs significantly from the expected distribution. Thus, the proportion of HbS in heterozygotes in these populations may be considered to be binomially distributed.

What do G_1 and G_2 represent? One hypothesis would suggest that they are β-thalassaemia-like genes which selectively diminish β^S but not β^A production; a binomial distribution of the proportions of HbS would result. No β-thalassaemia gene affecting the synthesis of a β-chain structural mutant has, however, been definitely demonstrated. Moreover, higher HbA_2 levels might be expected but only modest elevations have been observed in heterozygotes with low proportions of HbS. There seems to be no evidence to support this possibility. A second hypothesis proposes that variations in the number of β-globin gene loci account for variations in the proportion of HbS in hererozygotes[15]. Both the available genetic data[16–18] and direct measurement of the number of β-globin genes[19] indicate, however, the existence of only a single β-chain locus.

The simplest remaining explanation is that G_1 and G_2 represent the number of active α-globin structural genes. Under this hypothesis, G_1 and G_2 would be chromosomes with

*G. Brittenham *et al.*, unpublished

1 and 2 active α-globin loci, respectively. G_1G_1 would correspond to an α^A/α^A genotype, G_1G_2 to $\alpha^A/\alpha^A\alpha^A$, and G_2G_2 to $\alpha^A\alpha^A/\alpha^A\alpha^A$. A net α-chain production deficit would be found in individuals with less than 4 α genes. In at least some cases, α-thalassaemia (α-chain production deficit with unbalanced α/β synthesis) results from deletion of the α-chain gene locus. It has been demonstrated that a low proportion of HbS is found in some heterozygotes with α-chain deficiency due to α-thalassaemia[20,21]. Calculation of the absolute amounts of the Hb fractions per cell (MC[HbA] and MC[HbS]) demonstrates that the absolute amount of HbA does not differ significantly between those with high or low percentages of HbS. Only the amount of HbS (MC[HbS]) is decreased in those with a low percentage of HbS[22]. This result is evidence that α chains have a greater affinity for β^A chains than for β^S chains, a hypothesis that was suggested over a decade ago[23] and is supported by recent *in vitro* data[24]. Thus, the proportion of HbS can reflect the availability of α chains, which can be, in turn, a function of active α-globin gene number.

α-Thalassaemia may not be an invariant finding in those individuals with a low proportion of HbS. A recent study has presented evidence that α/β synthesis may be balanced in individuals with two or three α-globin genes[25]. Furthermore, balanced globin synthesis has been reported in two heterozygotes with 25 and 28% HbS[11]. In the absence of other conditions affecting globin synthesis, a low proportion of HbS can indicate a deficit in α-globin chains due to a decreased number of active α-globin structural genes, with or without an associated imbalance in globin synthesis (α-thalassaemia).

If the proposed interpretation of the genetic model is correct, there should be a close correspondence between model predictions of α^A and $\alpha^A\alpha^A$ gene frequencies and estimates by other techniques. The level of Bart's Hb (γ_4) in cord blood specimens has been used to estimate the number of α-chain loci. In the same US black population reported in study 2 (ref. 7; Table 2), analysis of 14,058 cord blood samples has provided frequencies of 0.162 for α^A and 0.838 for $\alpha^A\alpha^A$ genes[26]. These values are almost identical to the estimates of 0.152 for α^A and 0.848 for $\alpha^A\alpha^A$ derived from analysis of the observed distributions of the percentages of HbS (Table 2). Other evidence, including measurement of the proportion of α-chain variants[18], the number of α-chain variants in certain individuals[18], and direct measurement of the number of α-globin genes in DNA hybridisation experiments[19], indicate that the α-chain locus is duplicated in some populations. Finally, recent family studies have provided further evidence that the proportions of β-chain variants in heterozygotes are a function of the number of α-chain loci[27].

The existence of a chromosome with no active α-chain loci has recently been demonstrated in American blacks[26,28] and is well documented in Asians[29]. The genetic model may be extended by letting G_0, at frequency p_0, represent this chromosomal condition. For a population in Hardy–Weinberg equilibrium and having three types of chromosome, with no, one and two α-chain loci, the genotype frequencies are given by the binomial expansion $(p_0+p_1+p_2)^2$ as shown in Table 3. The distributions of the proportions of HbS reported for the heterozygotes of 11 of 12 Guinean and Angolan populations[30] fit the predictions of the three chromosome type model (data not shown, available from the author). This result must be interpreted with caution, however, because the conditions of this study[30] precluded detection of hydrops fetalis, HbH disease or α-chain variants.

Table 3 Phenotypes and genotypes: model with three genetic units (G_0, G_1 and G_2)

Phenotype (% HbS) Mean	Range	Model genotype	Frequencies
(Hydrops fetalis)		G_0G_0	p_0^2
17	(15–19)	G_0G_1	$2p_0p_1$
(HbH disease)			
25	(20–29)	G_0G_2, G_1G_1	$2p_0p_2+p_1^2$
33	(30–36)	G_1G_2	$2p_1p_2$
40	(37–50)	G_2G_2	p_2^2

The genetic model presented here suggests that human populations are polymorphic for the number of active α-globin genes. With differing proportions of HbS in sickle-cell trait, the absolute amount per cell of HbS, but not HbA, varies, supporting the *in vitro* evidence that α chains have a greater affinity for β^A chains than for β^S chains. The proportion of HbS can, therefore, reflect the availability of α chains which, in turn, can be a function of the number of α-globin genes. By using the proportion of HbS as an indicator of α-globin number and postulating that populations are in Hardy–Weinberg equilibrium for chromosomes with two, one and no α-chain loci, the distribution of the proportion of HbS can be accounted for in 24 of the 25 populations reviewed.

Absolute visual threshold and scotopic spectral sensitivity in the tawny owl *Strix aluco*

IT has long been assumed from considerations of the behaviour of owls that the vision of these species is much more sensitive than that of man. Experimental determinations of the absolute visual sensitivity of these birds have provided evidence in support of this view, suggesting that visual sensitivity in owls is of the order of 10 to 100 times (+1.0 $\log_{10}$ to +2.0 $\log_{10}$ units) that of man[1,2]. Owing to calibration problems, however, these values were probably inaccurate by at least a factor of 10 (refs 1, 2). I report here that in at least one highly nocturnal owl species, visual sensitivity is only slightly higher than that of man, and that the increased sensitivity can be attributed to optical factors rather than to any increase in sensitivity at the retinal level. This suggests that retinal mechanisms in both man and owl have reached the ultimate in sensitivity for the duplex retinas of terrestrial vertebrates.

Determinations of human absolute sensitivity in ideal experimental conditions suggest that once a photon has been absorbed by the photoreceptors, the human retina comes close to the theoretical limit of sensitivity[3,4]. Hecht, Shlaer and Pirenne[3] have shown that single photoreceptors can respond to the absorption of a single quantum of light and that the retina as a whole is capable of detecting small brief stimuli when only about 10 light quanta are absorbed by the receptors. The emphasis in these figures is, however, on absorbed quanta and a sensitivity increase over that of man could be achieved at the retinal level by increasing the probability of quantum catch in the receptors. This could be effected by enlarging the photoreceptor outersegment and/or by increasing the density of pigment contained therein[5].

Considerable improvement in sensitivity of the eye as a whole, as opposed to that of the retina alone, could be achieved by an increase in the relative proportion of quanta falling upon per unit retinal area for the given stimulus external to the eye. (Approximately 90% of quanta incident on the human cornea are absorbed or scattered before reaching the retinal receptors[4,6].) This could be achieved by increasing the light gathering power (photographic speed) of the eye and by increased transmission of light through the optic media.

I determined the absolute sensitivity threshold to achromatic light and the scotopic spectral sensitivity of two tawny owls, *Strix aluco,* using a training procedure designed to produce a high degree of behavioural control by the visual stimuli close to threshold. For comparison, the absolute thresholds of two human subjects were determined in as near identical conditions as possible.

The owls were maintained as described previously[7], and a two-choice simultaneous discrimination procedure with appetitive reinforcement was used. The training procedure and apparatus were modified versions of those used previously with the same subjects[7,8]. One important modification was the addition of a gentle air flow directed towards the bird around the response bars while a trial was in progress, and around the food dish during reinforcer presentation. This air flow was used as a cue to increase behavioural control of the animals while responding in total darkness[9]. All surfaces inside the response chamber were painted matt black. The whole apparatus (which was mounted in a light-proof room) was made light tight and during training was covered by a large bag of heavy gauge black polythene sheeting.

Table 1 shows absolute threshold data for achromatic stimuli for the owls and humans after different length dark-adaptation periods. For the owls training and testing lasted approximately 12 months. Sessions in which no light was presented produced a chance level of discriminative performance suggesting that the animals' behaviour was not under the control of stimuli other than the stimulus lights.

As found in other vertebrates dark adaptation in the owl is close to asymptote after 30 min. Comparison with previously published[4] human absolute threshold data for extended light sources (mean of 22 subjects = 0.75×10^{-6} cd m^{-2} range 0.4–2.0×10^{-6} cd m^{-2}) shows that the human thresholds recorded here were within the normal range. Clearly, the behaviourally determined absolute sensitivity of the owl is not as superior to that of man as has commonly been supposed. The normal range within which human absolute thresholds lie covers approximately 1.0 $\log_{10}$ unit, and the data presented here suggest that while the absolute threshold of the owl is probably below that of man the two species show considerable overlap in the distribution of their thresholds. The broadness, compared with that of man, of the owl scotopic spectral sensitivity function (Fig. 1), which has also been found electroretinographically[11], is probably attributable to the slightly increased *in situ* rod visual pigment density in the owl. The spectral locus of maximum sensitivity corresponds with the locus of maximum absorption of owl rod visual pigment (λ_{max} 503 nm). (Bowmaker, J.K. and Martin, G.R. in preparation).

It does not seem that the increase in owl sensitivity compared with that of man, is attributable in any large measure to differences in either pigment density or retinal neural mechanisms in the two species. Consideration of the light-gathering power of the tawny owl's tubular shaped eye suggests that as in the cat[12] (where the position is complicated by the presence of a tapetum) the difference in the light-gathering power of the human and owl eye is sufficient to account for the observed difference between owl and human absolute sensitivity. The minimum *f*-number (maximum pupil diameter) of the owl eye is 1.30 (in preparation), while that of man[13,14] is 2.10 producing a retinal illumination in the owl approximately 2.6 times that of man (compare mean absolute sensitivity difference (two owls compared with two humans) of approximately 2.5-fold). Thus it can be concluded that the human extrafoveal retina is of approximately equal sensitivity to that of other vertebrates considered to be highly nocturnal. The data also suggest that the human retina, along with those of the cat and the owl, has indeed attained the absolute limit of

Table 1 Absolute visual sensitivity threshold data for two humans and two tawny owls following various dark-adaptation periods

	Dark-adaptation period (min)	Threshold $\log_{10}$	Mean $\log_{10}$	Mean threshold calibrated (cd m^{-2})	Threshold relative to human
Owl (01)	30	3.54	3.56	0.84×10^{-6}	$\times 1.45(+.16 \log_{10})$
	60	3.64			
	90	3.49			
Owl (02)	30	3.96	4.04	0.28×10^{-6}	$\times 4.36(+.64 \log_{10})$
	60	4.17			
	90	4.00			
Human *a*	30	3.50	3.40	1.22×10^{-6}	
Human *b*	30	3.38			

Thresholds are shown in the arbitrary $\log_{10}$ units from which the calibrated values were determined. Subjects were dark adapted in the apparatus. The only light present throughout training and testing was the stimulus light. Length of stimulus presentation was determined by the latency of the subjects' response and was rarely more than 5 s even during blank probe trials when no stimulus light was presented. Reinforcers were presented during 10-s intertrial intervals signalled by a buzzer. Forty trials per daily session were used with a left–right Gellerman sequence and stimulus intensities presented in a quasi-random order according to a method of constant stimuli. Psychophysical functions (% trials correct per stimulus intensity) were constructed for each subject using between 40 and 100 trials per intensity and these were interpolated at the 75% correct point to give threshold values. Threshold data were accumulated after extensive training. The human subjects (male aged 27 yr; female, 26 yr) viewed the stimuli without fixation through a hole cut in the back of the owls' response chamber (stimulus subtense, 23 × 15°) and responded by closing a microswitch. Extensive practice was given. Fifty trials were recorded at each stimulus intensity and thresholds determined as for the owls. The stimulus light (correlated colour temperature 2850 K) was provided by a quartz halogen lamp (GEC 450, under-run from a constant current supply) back projected onto 12 × 8 cm (angular subtense at bird's perch, 48 × 34°) ground glass panels by an optical system similar to that described by Muntz and Northmore[10]. Light entered the apparatus through a 5-mm diameter hole (placed at the focal point of one of the lenses) in a light-proof box mounted behind the stimulus panels.

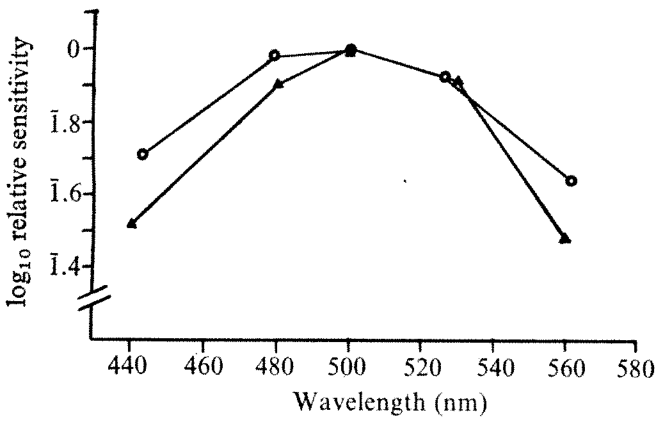

Fig. 1 Behaviourally determined scotopic spectral sensitivity of the tawny owl (○) (mean of two birds). Thresholds were determined using interference filters and the same procedure and apparatus as in the determination of absolute sensitivity to achromatic stimuli. For comparison the human CIE V_λ' function is also shown (▲). Sensitivity is expressed according to an equal quantum intensity base. For calibration of stimuli the following were used: an Hilgar–Shwartz F.T. 17 thermopile placed at the first focus of the optical system to determine the relative energy available through the interference filters (Balzars, B40) and the density of high value neutral density filters *in situ*; an EMI photomultiplier with entrance window placed against the stimulus panels was used to determine the *in situ* density of the low value neutral density filters; a Shimadzu scanning spectrophotometer to determine the spectral transmission of the interference filters. An SEI photometer was used to determine the absolute luminance values of the stimulus panels with filters removed from the beam, and stimulus values at threshold were determined by calculation from the calibrated filter values.

sensitivity, at least for those terrestrial vertebrates with duplex retinas in which some kind of pattern vision is required at low light levels.

Man is typically used as the yardstick for interspecies comparisons of sensory capacities. To gain some appreciation of the adaptive significance of such capacities for the owl, however, a comparison with man is not particularly appropriate. Of more value is the comparison of the owls' sensitivity with that of a diurnal bird, such as the pigeon, *Columba livia*. This species, which is known to roost immediately on being placed in darkness, has an absolute sensitivity approximately 2.0 $\log_{10}$ unit (that is, 100-fold) lower than the owl[15]. This difference in sensitivity is probably attributable to a difference in retinal mechanisms since retinal illumination in the pigeon is approximately equal to that of man[16] (from observation of pupil diameter). Thus, although the vision of owls does not seem to be as highly sensitive as previously supposed, the sensitivity of these birds can be seen nevertheless to provide them with considerable behavioural advantage over other (diurnal) avian species at low light levels.

I thank Professor W. R. A. Muntz for advice and members of the MRC Vision Unit, University of Sussex, for discussions and assistance with calibrations. I thank the SRC for a Post-Doctoral Fellowship.

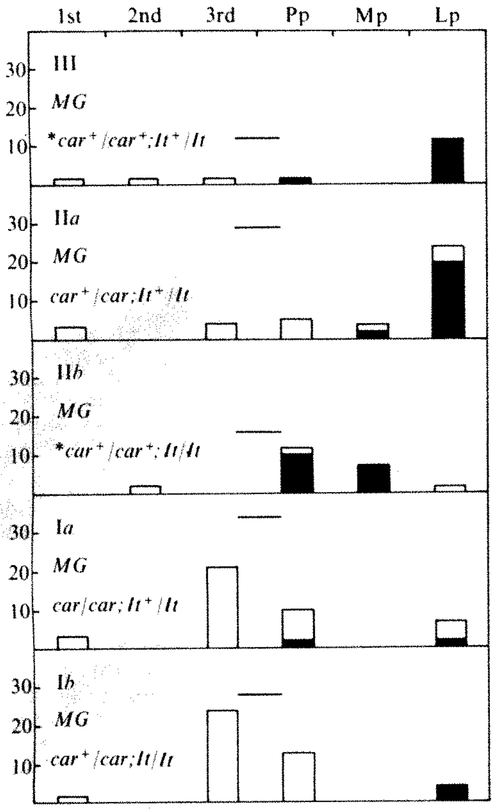
Maternal effects determine effective lethal phase of *carnation–light* synthetic lethal in *Drosophila melanogaster*

GENETIC conditions which preclude development to the reproductive stage (lethal factors) include dominant and recessive Mendelian units, genomic imbalance and gene interaction. Determination of the ontogenetic phase at which each lethal factor inflicts atypical development and death (effective lethal phase[1]) provides an opportunity for study of specific genetic requirements for normal development. I describe here maternal effects which determine the effective lethal phase (ELP) of a synthetic lethal[2] produced by the interaction of two non-lethal eye-colour mutations, *carnation* (*car*) and *light* (*lt*), in *Drosophila melanogaster*.

Penetrance of the lethal interaction of the *car* (position 62.5 on the X chromosome) and *lt* (position 55.0 on the second chromosome) genes is complete such that all *car-lt* double mutants (*car*/*car* : *lt*/*lt* and *car*/Y : *lt*/*lt*) die before eclosion. Both mutations cause a general reduction in pteridines and ommochrome precursors in larvae and adults when compared with wild type. Compound accumulations are similar to wild type during pupal stages[3].

The influence of the maternal genotype on the ELP was determined by examining the stage of developmental arrest of *car-lt* offspring from matings in which the number of car^+ and/or lt^+ genes varied in the mother. As Fig. 1 shows, a general trend is apparent—as the number of maternal car^+ and lt^+ genes increases, the later developmental arrest occurs in *car-lt* offspring. Yet, a comparison of data presented for crosses II*a* and II*b* indicates that the stage of developmental arrest is not solely dependent on the number of maternal car^+ and/or lt^+ genes. Females homozygous for *lt* produce synthetic lethal offspring which die at early pupal stages (cross II*b*), whereas those from females heterozygous at *car* and *lt* loci die at late pupal stages. A synergic relationship therefore exists between maternally derived car^+ and lt^+ gene products. The difference in ELP in offspring from crosses I*b* and II*b* suggests that the car^+ gene is semidominant with respect to lethal phase determination. The appearance of the semidominant behaviour of car^+ in crosses II*a* and III may be masked by the fact that the late pupal stage is the final stage obtainable by *car-lt* double mutants regardless of the maternal genotype. A test cannot be made of the dominance relations of lt^+ with respect to survival of synthetic lethal offspring. A comparison of crosses I*a* and I*b* indicates that maternal car^+ and lt^+ gene products have a similar influence on determination of the lethal phase of larvae. The relative infrequency of second-instar lethality is in agreement with other investigations[4,5]. No differences between sex and lethal phases were observed in any cross. Whether activity of maternal car^+ or lt^+ genes eliminates the cause of larval death of *car-lt* double mutants or merely prolongs the onset of a common developmental crisis is not known. Synthetic lethal larvae from crosses I*a* and I*b* show no gross abnormalities. Pharate adults from crosses II*a* and III, however, show abnormal development of internal genital disk derivatives (males) and incompletely developed abdominal tergites (males and females).

It is generally agreed that each lethal factor defines a particular ELP (monophasic) as embryonic, egg-larval



*attached-X chromosome

Fig. 1 Number of *car-lt* double mutants (shaded) and unclassifiable (open) offspring dying at various stages from crosses in which the maternal genotype (MG) included various numbers and/or combinations of car^+ and/or lt^+ genes. The paternal genotype was *car*/Y; lt^+/lt (plus appropriate marker genes described below) for each cross. Eggs collected from females (aged 2–6 d) were placed in culture tubes (6×50 mm), two per tube, containing 0.1 ml of standard medium. Each tube was examined periodically and scored as to condition of eggs (hatched or unhatched), larvae (instar: 1st, 2nd or 3rd) and pupae (stage). Pupae which failed to eclose within 15 d of egg collection were scored as to the stage of developmental arrest: prepupa (Pp), midpupa (Mp, pupation to onset of bristle pigmentation), late pupa (Lp, bristle pigmentation to pupa ready to emerge). Dead larvae, Pp, or pupae were classified as to genotype when possible by appropriate marker genes (*y, lt, B, f, Cy*) as described by Lindsley and Grell[12]. Fertility ratios were determined thus allowing computation of the expected number of *car-lt* double mutants for each cross. This number is represented by a horizontal line (————) in each component of the figure.

(boundary), larval-pupal (boundary) or late pupal[4] in which the degree of genetic change is inversely related to the duration of survival[6]. A direct relationship between genetic complement and time of death was demonstrated by Shannon *et al.*[7] where a consistent ELP is observed within a given genetic complementation group. A multiphasic lethal pattern is sometimes observed when environmental factors (crowding and so on), genetic background, variations in pentrance and maternal genotype cause some individuals to die at a stage earlier than the characteristic lethal phase[4,6–8]. Li[9] reported maternal effects determining survival of all offspring of *Plexate, Minute-1, plexus* and haplo-IV females. Each case, however, seems to be related directly to the mother's ability to produce functional eggs of all Mendelian classes. Because fertility ratios computed in this study show no consistent relationship to the number of maternal car^+ or lt^+ genes, it can be assumed that the ability of the females used to produce functional eggs *per se* is unrelated to the time of developmental arrest in *car-lt* double mutants. Rather, when sufficient contributions are made by maternal car^+ and lt^+ genes, *car-lt* double mutants transcend the larval lethal phase (crosses II*a*, II*b* and III) and enter the radically different developmental phase of metamorphosis.

Maternally derived lt^+ gene products which alter Malpighian tube pigmentation in *lt/lt* offspring from lt^+/lt mothers[10] may be involved in lengthening survival time in *car-lt* double mutants. It is improbable, however, that these products directly lengthen survival beyond pupation (as in crosses II*a* and III), for the maternal influence on pigmentation ceases before pupation[11]. The chromatographic-fluorometric procedure used to assess the pigment maternal effect resulting from activity of the lt^+ gene was used to determine whether a similar maternal effect is associated with car^+. Results were inconsistent with such an effect.

The viability of *car/car* or *lt/lt* genotypes indicates that their alleles (car^+ or lt^+) are not necessary for normal development unless homozygosity for the mutant allele exists at the other locus. In these cases survival depends on the presence of car^+ or lt^+ gene products by at least the early third-instar stage. In *car-lt* double mutants these products are maternally supplied whereas in survivors (car^+/car : *lt/lt* or *car/car* : lt^+/lt for example) these gene products are supplied by the organism's own genome as well as that of the mother.

Age- and region-dependent concanavalin A reactivity of chick wing-bud mesoderm cells

MORPHOGENETIC potential of embryonic chick limb mesoderm cells declines with time beginning at approximately stage 24 of development[1]. This decline occurs in a proximo-distal direction[2]. Accompanying the loss of morphogenetic potential there is an age-dependent decline in the ability of limb and axial mesoderm to sort from one another in a randomised mixture of cells[1,3,4]. Due to the age-dependent decline in both morphogenetic potential and the sorting ability of the limb mesoderm cells, it has been suggested that the decline in morphogenetic potential may be related to changes occurring at the cell surface[5]. Cell surface carbohydrate moieties have been postulated to play an integral part in cellular interactions[6]. Because of their high degree of carbohydrate-binding specificity[7], plant lectins, such as concanavalin A (con A), *Ricinus communis* agglutinin (RCA), and wheat germ agglutinin (WGA), have been used to monitor cell surface changes which occur during development[7–13]. These changes manifest themselves as differences in lectin-induced agglutinability of cells, and changes in number and distribution of lectin binding sites on the cell surface. This study was designed to determine if there were cell surface changes accompanying the decline in morphogenetic potential of the limb mesoderm cells, which could be detected by the use of plant lectin probes. We report here that there is a slight increase in RCA-induced agglutination of chick wing-bud mesoderm cells with increasing developmental age. There is also a significant age-dependent, proximo-distal decline in the susceptibility of chick wing-bud mesoderm cells to con A-induced agglutination between stages 19 and 26 of development. As such, there is a spatial as well as a temporal correlation between the decline of con A agglutinability and the decline of the morphogenetic potential of the chick limb-bud mesoderm cells.

Zwilling has suggested that the events of limb development can be divided into two phases: a morphogenetic phase and a phase of cytodifferentiation[1]. Limb mesoderm cells have a set of properties during the morphogenetic phase which are responsible for the establishment of general limb form[1]. The ability of limb mesoderm to express these morphogenetic properties or potential declines in a proximo-distal direction from a peak at stage 19–20, until the morphogenetic potential is lost at about stage 26 (refs 1, 2). During the interim period, the morphogenetic potential of the limb mesoderm cells in a single limb bud is region-dependent[2]. Table 1 shows that the agglutination of chick wing-bud mesoderm cells with WGA (125 μg ml^{-1}) is nearly complete and not age-dependent. RCA (125 μg ml^{-1}) induces slightly greater agglutination of cells from older wing buds than of those from younger wing buds. In contrast, treatment with con A at the same concentration induces a significantly greater degree of agglutination of mesoderm cells derived from whole stage 19–20 wing buds than it does of mesoderm cells derived from whole stage 25–26 wing buds. The disparity between the morphogenetic potential of proximal and distal mesoderm in a single limb bud is greatest at stage 25 of development[2] (Table 1). Limb mesoderm cells from the proximal third of a stage 25 wing bud are significantly less susceptible to con-A induced agglutination than are those from the distal third. Furthermore, the difference in susceptibility to con A-induced agglutination between mesoderm cells from the proximal and distal thirds of the stage 25 wing-bud, is greater than that between cells derived from whole stage 19–20 and 25–26 wing buds. This is not surprising since whole stage 25 and 26 limb buds contain mesodermal cells of relatively high con A agglutinability in their distal region.

Table 2 Specific binding of ^{3}H-con A to stage 25 wing-bud mesoderm cells

Region of wing bud furnishing mesoderm cells	Specific binding of ^{3}H-con A (c.p.m. per mg protein)
Distal third	20,616±910 (n = 5)
Proximal third	20,844±700 (n = 7)

Single cell suspensions of proximal and distal stage 25 wing mesoderm were obtained as described in the legend for Table 1. Binding experiments were performed at 0 °C to minimise endocytosis of bound con A. The binding reaction was done in a 1 ml volume containing 5 × 10^{6} cells, 125 μg unlabelled con A and 1 μCi ^{3}H-con A (specific activity 41 Ci mmol^{-1}) (New England Nuclear). Controls contained the same components plus 0.1 M α-methyl-D-glucose (Sigma) to indicate the non-specific binding of con A. The amount of binding observed in the controls was subtracted from the values of total binding to give the amount of specific binding. The tubes containing the reaction components were kept at 0 °C for 1 h with mixing at 15-min intervals, after which they were centrifuged at 2,500 r.p.m. for 5 min. After the supernates were removed, the pellets were washed three times in 2 ml of ice cold Tyrode's solution to remove any unbound ^{3}H-con A. The pellets were then dried and dissolved in 1 ml of 1 M NaOH. Aliquots were taken for scintillation counting and protein determinations by the Lowry method[17]. Values are mean ± s.e.m.

It is not yet possible to draw conclusions regarding a causal relationship between the cell-surface changes (suggested by the decline in con A-induced agglutinability) and the loss of the morphogenetic potential of the limb mesoderm cells. There is evidence, however, of a positive temporal as well as spatial correlation between these two phenomena.

To determine the basis of the differential con A reactivity between the cells from the proximal third and those from the distal third of the stage 25 chick wing bud, the relative con A binding capabilities of the cells from these two regions were assayed using ^{3}H-con A. These experiments indicate that there is no significant difference between the amounts of ^{3}H-con A bound by the cells from these two regions (Table 2). This is in contrast to a decline with increasing developmental age, in the amount of con A bound by normal mouse limb mesoderm cells between days

Table 1 Correlation of lectin-induced agglutinability of whole stage 19–20 and stage 25–26 wing-bud mesoderm cells and mesoderm cells from proximal and distal thirds of stage 25 wing buds with their morphogenetic potential

Region and stage[18] of wing bud furnishing mesoderm cells	%Specific agglutination with RCA*	%Specific agglutination with WGA*	%Specific agglutination with con A*	Morphogenetic potential†

*Mesoderm from whole wing buds of stage 19–20 and stage 25–26 white leghorn chicken embryos and mesoderm from the proximal or distal third of stage 25 wing buds was collected by dissecting the wing buds from the embryos in a dish containing Tyrode's solution. The proximal and distal thirds of the stage 25 wing buds were kept separate. The whole wing buds or the proximal or distal segments were transferred to depression dishes in which they were incubated with 2% trypsin (Nutritional Biochem.)+1% pancreatin (Nutritional Biochem.) in Tyrode's for 15–20 min at 37 °C to loosen the ectoderm. The ectoderms were removed, and after washing with Ca^{2+}-free Mg^{2+}-free Tyrode's (CMF), the mesoderm was cut into fragments and incubated in CMF containing 0.02% EGTA (ref. 9) (Sigma) at 37 °C for 45 min. After this treatment, the EGTA solution was replaced with Tyrode's containing 10 μg ml^{-1} DNase (ref. 9) (DNase–Tyrode's) (Nutritional Biochem.). After transferring the mesoderm fragments to Falcon plastic test tubes containing 2 ml of DNase–Tyrode's, single-cell suspensions were obtained by mild agitation. The number of cells in each suspension was determined with a haemocytometer and adjusted so that after addition of the appropriate plant lectin (Sigma) and its specific sugar inhibitor (Sigma) in DNase–Tyrode's to control cultures, and the appropriate plant lectin in DNase–Tyrode's to the experimental cultures, each gave a final cell density of approximately 2.5 × 10^{6} cells ml^{-1} in a total volume of 3 ml. The final concentration of plant lectin was 125 μg ml^{-1}. To control for nonspecific agglutination, α-methyl-D-glucose, *N*-acetyl-D-glucosamine, or α-lactose (all Sigma) were added to control cultures containing con A, WGA, and RCA respectively. The final concentration in the control cultures of these specific inhibitors was 0.1 M. The cells were incubated in siliconised 25 ml Erlenmeyer flasks for 30 min at 37 °C in a gyratory shaker water bath, operating at 70 r.p.m. After incubation, samples were examined in a haemocytometer and single cells remaining counted. The disappearance of single cells from the cell suspensions was used as a measure of cell agglutination.

*Percentages of nonspecific agglutination were subtracted from the values of total agglutination to give the percentages of specific agglutination. Values are mean±s.e.m.

†Percentage of grafts, containing mesoderm cells taken from specific stage and region, which formed complex limb structures as determined by the assay of Zwilling[16]. Values for whole limbs obtained percentages for component parts[2].

11 and 12 of development[14], and an increase in the number of binding sites for con A with increasing developmental age in embryonic chick neural retina cells between days 8 and 10 of development[11]. In the chick limb, mouse limb, and chick retina systems, these changes in the number of con A binding sites with increasing developmental age are all accompanied by a decrease in con A-induced agglutinability. Therefore, it seems that some cell membrane or surface property, other than the number of con A binding sites, is responsible for the observed differences in con A-induced agglutinability. The mechanism responsible for the differing response to con A treatment in our system may involve the lateral mobility of the con A binding sites within the plane of the plasma membrane since the clustering of these sites has been shown to accompany increased agglutination in other systems[11,15].

Morphogenesis involves the interaction of large numbers of cells. Since a primary site of such interactions is at the cell surface, an understanding of the cell-surface changes which occur during development as well as how they relate to changes in the morphogenetic potential of cells, will be of significance to our understanding of morphogenesis in general.

Monogamous T helper cell

HUMORAL antibodies are produced by lymphocytes of bone-marrow or bursal origin (B cells). Some antigens are apparently capable of stimulating B cells and inducing a response directly but many other antigens are dependent on the cooperative help of lymphocytes of thymic origin (T cells). There are at least two forms of such cooperation between B and T cells. One type of cooperation is 'non-specific' where T cells once activated by specific antigen release a nonspecific factor which can then facilitate the responses of B cells to certain other non-related antigens[1]. The other well studied cooperative mechanism is known as 'specific cooperation' and classically this has been analysed with the use of 'hapten-carrier' systems[2]. The exact nature of this cooperative event is not known. It may be that co-operation occurs through widely diffusible specific factors released by T cells, or alternatively the cooperating T and B cells may need to come into close or direct contact. We have studied helper T-cell function in a microculture system with the aim of determining whether a single helper T cell could activate one or many B cells. Experiments of this type have previously been performed by repopulating mice with limiting numbers of immunocompetent cells and examining the resulting foci of antibody activity. When T cells were the limiting population some have found these foci to be heterogeneous[3] and others have found them to be monoclonal[4,5]. Similar *in vitro* studies have also suggested marked restriction in the B-cell response where T helper cells were limiting[6]. Here we present direct evidence to support the findings demonstrating restriction. We conclude that in the conditions used, one specific helper T cell cooperated with one B cell only.

Table 1 Number of clones observed in each well compared with numbers expected for random distribution of T cells

No. of wells estimated to contain the following numbers of TNP-specific B-cell clones if 1 T cell activates 1 B cell†	19.28	21.56	12.06	4.53	1.28	0.28

*Analysis of the number of wells containing different numbers of B cell clones from the 59 samples analysed in Fig. 2.

†If we hypothesise that one T cell activates one B cell then the clones would be distributed according to the Poisson distribution of T cells getting into wells. A total of 66 clones as observed would be expected to distribute as shown.

The culture system used in the experiments was the

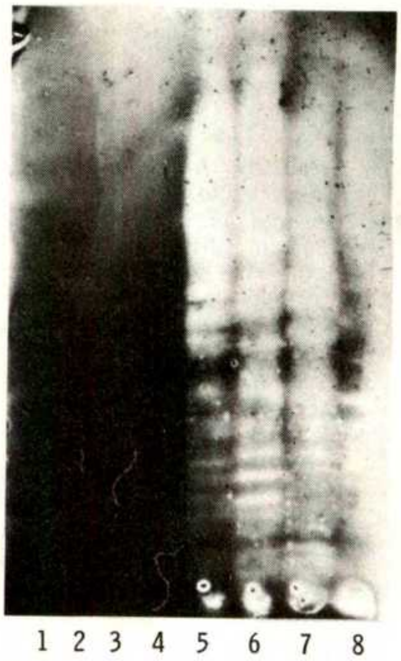

Fig. 1 Anti-TNP spectrotypes obtained from supernatants of *in vitro* microcultures. Antibody was visualised by overlaying the gel with haptenated red blood cells and complement[15]. Microcultures were performed as before[5]. B cells were obtained from mice primed three months previously with 500 µg of TNP-ovalbumin in Freund's complete adjuvant and subsequently boosted twice with 200 µg of soluble antigen. The last boost was performed two weeks before the experiment. The spleen cells from these mice were treated with anti θ and complement to remove T cells. T cells were derived from mice primed one month previously with 250 µg of KLH in Freund's complete adjuvant and boosted with 200 µg of soluble KLH 6 d before killing. The spleen cells from these mice were enriched for T cells by passage through nylon wool. 1.5×10^5 B cells were cultured with antigen (TNP-KLH) in multiple wells containing 10 µl of medium. Samples 1–4 were from four cultures having no T cells. Samples 5–8 were from wells having 5×10^4 T cells per well.

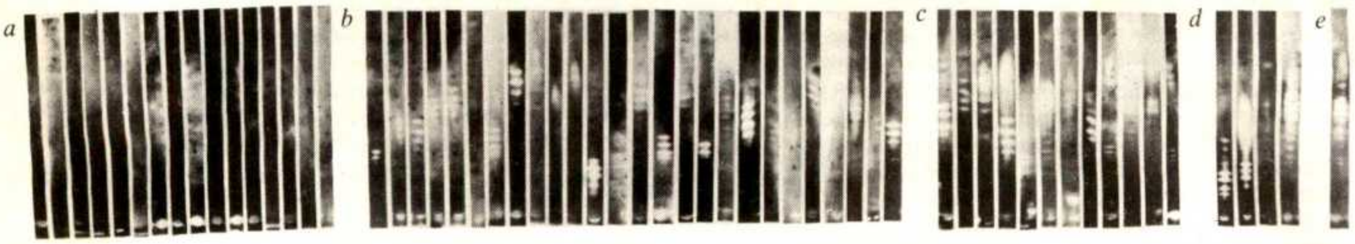

Fig. 2 Anti-TNP spectrotypes from supernatants of *in vitro* microcultures. Antibody visualisation and culture conditions are described in Fig. 1 but in this case 1.5×10^5 B cells and 2.5×10^3 T cells per well were used. 59 individual supernatants were analysed and samples grouped according to the numbers of different spectrotypes (a,b,c,d,e, = 0,1,2,3,4 spectrotypes respectively).

microculture system devised by Lefkovits[7]. The technical procedures adopted for studying the functions of single helper T cells have been described before and it was shown that one single helper T cell was sufficient to activate a B cell response to antigen[8]. Levels of hapten specific B cells were used such that each well contained more than 5 B cells and then T cells were titrated to a level such that many wells would contain 0 or 1 specific helper T cell. After 7 d of culture the supernatants from the cultures were analysed by isoelectric focusing (IEF). By this method different spectrotypes are interpreted as representing the products of different B-cell clones. Figure 1 shows that when no T cells were added all wells were negative, and that when a high number of T cells were added to each well the responses were so heterogeneous that the exact number of clones could not be accurately counted but we can say that there were more than five per well. At a T-cell input of 2.5×10^3 T cells per well, then 16 out of 59 wells which we sampled were negative. With this number of negatives it can be estimated that the majority of the positive wells would contain only one helper T cell. The number of clonal products observed in each of the positive wells of this tray were then counted. In Fig. 2 we show that in 59 wells sampled a total of 66 B-cell clones were generated. If we now hypothesise that these B-cell clones were the result of a 1 T cell : B cell interaction then the clone numbers would be expected to segregate in the wells according to a Poisson distribution of T cells, as these are the cells which are randomly distributed. Table 1 shows the numbers of clones observed in each well compared to that which would be expected by a Poisson distribution of the total 66 clones, and it can be seen that the fit is very close ($\chi^2 = 1.76$). Thus the most accurate estimate we can derive from this data is that one T cell is only able to cooperate with a single hapten specific B cell. The number of wells containing multiple clones can be accounted for by chance distribution of T cells, however, we cannot exclude the possibility that a minority of the T-cell population could cooperate with more than one B cell.

This finding shows that observations which indicated marked restriction in the number of B cells helped by a single T cell were indeed the consequence of a monogamous behaviour of helper T cells. The discrepancies with data showing heterogeneity[3] may be the result of the nature of the antigen used since in situations where heterogeneous foci are detected, particulate antigens have been used and with particulate antigens T cells are able to produce a soluble factor (NSF) which can easily replace helper T cells.

The finding that one T cell only reacts with one B cell does not support the idea that this cooperation has occurred through specific factors unless the activity of these factors is short ranged. Either way, the data is not compatible with the concept of widely diffusible specific mediators[9,10].

An alternative explanation is that there may be subsets of B and T cells such that each T cell is able to react directly with or release factors which could react with only a certain proportion of the possible B cells. There is some evidence that individual T cells release NSF which is specific for a subpopulation of the B-cell repertoire[11] and it is possible that similar restrictions are placed on specific helper T cells. One situation where specific helper cells have been shown to be selective is in the case of allotype specificity[12]. The same selectivity may exist among T cells for immunoglobulin class[13,14].

If single T cells could be presented with a large enough range of B cells it should be possible to over-ride any 'matching' restrictions. In our experiments we can only be assured of 5–12 B cells per well and so far attempts to enrich the B cell population for trinitrophenol (TNP) specific B cells have only increased the numbers of hapten specific B cells by two- to fourfold and this did not affect the observed restriction. Enriching for hapten specific B cells would also rule out the possibility that the T cells are not able to 'find' more than a very near B cell.

The third possible explanation for the result is that cooperation between specific T and B cells requires cell-to-cell contact and that once this has taken place the T cell is then, somehow, rendered inactive towards other B cells. Should this in time be shown to be the correct explanation then it must be resolved just how two such rare antigen specific cells (T and B) could locate each other.

We thank Gill Kenny for technical assistance and Elizabeth Thompson for her assistance in analysing the data. This work was supported by the MRC.

Dissociation of effector functions in populations of activated macrophages

THERE is much evidence to indicate an important role for activated macrophages in resistance to malignant tumours and to infections caused by intracellular pathogens. Different investigators have found that activated macrophages may be distinguished from normal macrophages by either morphological, biochemical, or functional criteria, depending on the experimental design[1]. Functional criteria frequently cited are killing of intracellular organisms[2,3], inhibition and/or killing of tumour cells[4-6] and inhibition of proliferating lymphocytes[7,8]. Previous work in our laboratory has demonstrated that macrophages activated by several methods have always exhibited each of these three functional capacities. For example, macrophages activated by either chronic infection with C56 strain *Toxoplasma gondii* or by killed *Corynebacterium parvum* inhibited multiplication of *T. gondii*[9-11], DNA synthesis by tumour target cells[12,13], and mitogen- and antigen-specific lymphocyte transformation[14]. Whether different populations of activated macrophages which have been defined by one functional criterion always possess the other functional capacities of activated macrophages as well, however, has not been established. We report here that activated macrophages characterised by one functional criterion do not necessarily possess other functional characteristics of activated macrophages and that differences in functional capacity depend on the method used to activate the macrophages.

Three models for activating macrophages were used: *Trichinella spiralis* infection in C57Bl/6 mice (ref. 15 and E.J.W. and J.S.R., in preparation), C37 strain *T. gondii* infection in BALB/c mice[16] and C56 strain *T. gondii* infection in Swiss Webster mice[9]. Peritoneal exudate cells, used as a source of macrophages, were harvested and processed as previously described[17]. Macrophage monolayers were challenged with either El-4 tumour cells to test inhibition of tumour cell DNA synthesis[17] or RH strain *T. gondii* to test inhibition of intracellular multiplication[18].

Table 1 Tumour cell cytostasis and inhibition of intracellular multiplication of *T. gondii* by activated macrophages

Infection used to activate macrophages	Time after infection	Tumour cytostasis (CI)	Infected macrophages with multiplying *T. gondii* (%) Normal	Experimental	Activated
T. spiralis in C57B1/6 mice	2 weeks	98	96	98	0
C37 strain *T. gondii* in BALB/C mice	19 weeks	94	98	98	0
C56 strain *T. gondii* in Swiss Webster mice					
0 h incubation	16 weeks	99	98	0	—
24 h incubation	16 weeks	−14	99	1	—

Mice infected with *T. spiralis* were used 7–28 d after infection, those with C37 strain *T. gondii* infection at 19 weeks after infection, and those with C56 strain *T. gondii* infection 3–6 months after infection. Macrophages from the C56 strain *T. gondii*-infected mice were tested either immediately or after 24 h of *in vitro* incubation. To test tumour cell cytostasis by macrophages, 8 to 9×10^5 peritoneal exudate cells from appropriate mice were allowed to adhere for 3 h to 6-mm wells of 96-well microtitre plates (Flow Laboratories). The wells were then washed thoroughly with saline to remove nonadherent cells. E1-4 tumour cells (2×10^4 in 0.2 ml medium 199 with penicillin 100 IU ml^{-1}, streptomycin 100 μg ml^{-1}, and 10% heat-inactivated foetal calf serum) (M199-FCS) were added to each well. Incubation was carried out for a total of 24 h at 37 °C. Six hours before termination of the culture, the wells were pulsed with from 0.5 to 1.3 μCi (^{3}H)TdR (specific activity 6 Ci mmol^{-1}; Schwarz–Mann). The cells were collected with a MASH II harvester (Microbiological Associates) and then counted in a scintillation spectrophotometer. A cytostatic index (CI) was defined as $((N-A)/N)\times100$ where N is c.p.m. of tumour cells plus normal macrophages and A is c.p.m. of tumour cells plus activated macrophages. To measure inhibition of intracellular multiplication of *T. gondii* by macrophages, macrophage monolayers were prepared as previously described[17] and then challenged with 2×10^6 RH strain *T. gondii* trophozoites in M199–FCS for 1 h. The monolayers were washed and allowed to incubate in M199–FCS for 18–24 h. The slides were washed, fixed and stained with Giemsa stain. The percentage of infected cells with multiplying *T. gondii* was determined by light microscopy. Normal macrophages were from unimmunised mice; activated macrophages were from mice chronically infected with C56 strain *T. gondii.*

Experiments measuring the ability of macrophages to inhibit tumour cell DNA synthesis and to inhibit intracellular multiplication were run in parallel. In all experiments, macrophages from immunised mice were compared with both macrophages of normal mice (which do not inhibit DNA synthesis of El-4 tumour cells or inhibit intracellular multiplication of *T. gondii*) and macrophages from mice chronically infected with C56 strain *T. gondii* (which inhibit both).

The results are shown in Table 1. Macrophages from both *T. spiralis*-infected mice and C37 strain *T. gondii*-infected mice had the capacity to inhibit tumour cell DNA synthesis. These same macrophages were unable to prevent intracellular multiplication of *T. gondii*. For *T. spiralis*-infected mice, the dichotomy between the two functional capacities was observed in mice infected with from 200–530 larvae (significant mortality occurred above 530 larvae) and from 7 to 28 d after infection. For mice infected with C37 strain *T. gondii*, the dichotomy was observed at 19 weeks after infection.

Macrophages removed from mice infected with C56 strain *T. gondii* and challenged immediately inhibited both DNA synthesis by tumour cells and intracellular multiplication by *T. gondii*. After macrophages had incubated *in vitro* for 24 h, however, the capacity to inhibit DNA synthesis by tumour cells was lost, but the capacity to inhibit intracellular multiplication of *T. gondii* was retained. The density of the macrophage monolayers, which does affect tumour cytostasis, did not change significantly during *in vitro* incubation. Thus, macrophages in the first two experiments inhibited tumour cell DNA synthesis but not intracellular killing, whereas in the third experiment the converse was true.

Our results show that macrophages characterised as activated by one criterion may not satisfy other criteria of activation. That our observations were made in three unrelated experimental systems suggests that this phenomenon is common. The functional differences in different macrophage populations which we have observed may explain the variable results in previous studies and suggest that future publications that discuss activated macrophages should specifically state the criteria used to define the macrophages as activated.

Among the possible explanations for the variability in macrophage functions which we observed is the hypothesis that the functions of activated macrophages in a given population are identical at any one time. The functions of a given population, however, may vary with a number of factors, such as the nature of immunisation and the time after immunisation. Thus, for example, during an acute infection, when a maximum stimulus to activation occurs, all properties of activated macrophages may exist. These properties might be lost at different rates, and therefore at various times after infection only certain properties of activated macrophages are manifested.

A second hypothesis is that different subpopulations of effector macrophages with different functional capacities exist[19,20]. Thus, macrophages which inhibit tumour cell DNA synthesis may be distinct from those which inhibit intracellular multiplication. Our observation that in two experimental systems, inhibition of tumour cell DNA synthesis existed alone, whereas in the third inhibition of intracellular multiplication existed alone suggests this second possibility. The complete separation of functions we observed may be more consistent with the existence of different functional populations of activated macrophages.

The separation of the capacity of macrophages to inhibit multiplication by intracellular pathogens and to inhibit DNA synthesis by tumour cells should allow for more exact studies of the functions and biochemistry of activated macrophages.

Antiviral T cell-mediated immunity in Marek's disease

MAREK'S disease (MD) is a herpesvirus induced lymphoma of chickens characterised by transient virus replication in lymphoid cells and transformation of T cells[1]. Several mechanisms probably operate in resistance to Marek's disease, but there is indirect evidence that protective immunity is predominantly T-cell dependent[2] and comprises both antiviral[3] and anti-tumour[4] immune responses. Thus, a notable feature which distinguishes immunity to Marek's disease from immunity to other herpesvirus infections studied so far is that both effector and target cells are probably T cells and that both virus and tumour-specific antigens may act as targets for immunological attack. Using a plaque inhibition test as a measure of cell-mediated immunity, I show here that T cells obtained from immunised birds are sensitised to virus-specific antigens present at the surface of infected cells of both lymphoid and non-lymphoid origin. The results provide direct evidence for the role of T cells in eliminating infected leukocytes and in reducing the spread of Marek's disease virus (MDV) *in vivo*.

Sensitised lymphocytes were obtained from an inbred line of White Leghorns (Line 7) immunised at three weeks of age by intraperitoneal inoculation of 10^3 plaque-forming units (PFU) of cell-associated attenuated MDV (HPRS-16/att)[5]. Lymphocytes were isolated from peripheral blood by flotation in Ficoll–Hypaque and were washed three times in phosphate-buffered saline before use in plaque inhibition tests. Of the cells obtained, 90%–97% were small lymphocytes and 1.5%–2.0% were monocytes. Two types of tests were carried out. (1) Sensitised cells and MDV-infected cells (target cells) were mixed in suspension and were plated on monolayers of kidney cells derived from Line 7 chickens. Monolayers were washed after 24 h and plaques allowed to develop. (2) Monolayers of kidney cells were pre-infected with cell-associated MDV for 24 h before addition of sensitised cells. The first test was intended to study direct killing of lymphoid and non-lymphoid target cells. The second was originally designed to study predominantly the effect of sensitised cells on cell to cell spread of virus in monolayers of non-lymphoid cells.

The kinetics of plaque survival with increasing concentration of sensitised cells were consistent with a one-hit process of inactivation. This was noted in both types of tests and for both lymphoid and non-lymphoid targets (Fig. 1). Similar results were obtained in several experiments using sensitised lymphocytes derived from birds 20–70 d after immunisation. These results strongly suggest that sensitised cells act independently in preventing plaque formation and that target antigens are found on both infected lymphoid cells and on infected kidney cells. It has consistently been found that plaque inhibition was 1.5 to 2-fold greater when leukocyte-associated MDV was used as targets as compared with infected kidney cells. The differences observed in both types of tests using sensitised lymphocytes obtained 20–90 d after immunisation were significant ($P<0.01$ (seven experiments), Student's t test). The reason for this difference in susceptibility is not known, but it is possible that kidney-cell associated virus adapted to growth *in vitro* initiates infection more rapidly than leukocytes freshly isolated from infected birds. In this instance, it is known that the spread of MDV from infected leukocyte to kidney cells is delayed in at least a proportion of the cells and it is possible that the probability of plaque inhibition is greater for these cells

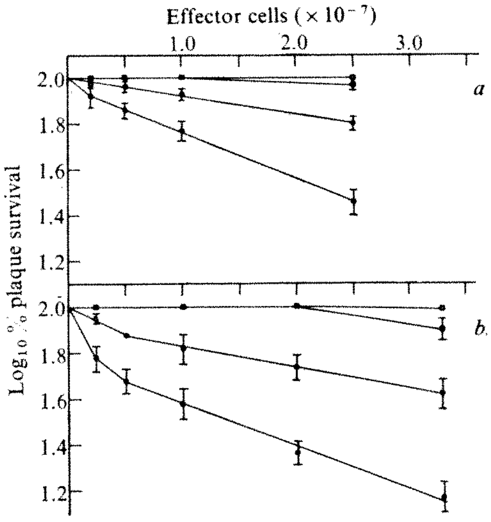

Fig. 1 Kinetics of plaque inhibition. *a*, Aliquots of 10^7 leukocytes obtained from Line 7 birds naturally infected with MDV or of 500 PFU of cell-associated MDV propagated in kidney cells derived from Line 7 birds were mixed in suspension with different numbers of sensitised leukocytes obtained from syngeneic birds. The mixture was plated for infective centres in duplicate on monolayers of syngeneic kidney cells grown in 50-mm Petri dishes. After 24 h at 37 °C, monolayers were washed and fresh medium added. Plaques were counted after 5 d. In this experiment, sensitised lymphocytes were obtained 50 d after immunisation. Lymphocytes used as controls to sensitised lymphocytes were obtained from normal Line 7 birds of identical age. Results shown are means of four estimations using lymphocytes obtained from different birds for each estimation, and are expressed as plaque survival relative to untreated cultures. Bar represents s.e.m. ●, Sensitised lymphocytes + leukocyte-associated MDV targets. ○, Sensitised lymphocytes + kidney cell-associated MDV targets. ■, Normal lymphocytes + leukocyte-associated MDV targets. □, Normal lymphocytes + kidney cell-associated MDV targets. *b*, Monolayers of Line 7 kidney cells in 50 mm Petri dishes were preinfected with leukocyte-associated MDV or with kidney cell-associated MDV. Medium was replaced after 24 h and sensitised or normal lymphocytes added. In this experiment, sensitised lymphocytes were obtained 30 d after immunisation. Cultures were refed after 48 h and plaques were counted 3 d later. Symbols as for Fig. 1*a*.

than for those which allow more rapid transfer of infectious virus. Thus, the survival curve obtained using monolayers pre-infected with leukocyte-associated MDV (Fig. 1*b*) probably reflects the survival of at least two cell populations differing in susceptibility to killing, each being inactivated with one-hit kinetics.

Although there was evidence of nonspecific inhibition using high concentrations of normal lymphocytes, the inhibitory effect observed at lower concentrations of sensitised cells was virus-specific. Thus, provided that the number of sensitised cells added to 50-mm dishes did not exceed 3×10^7, plaques formed by MDV only were inhibited. Vaccinia and herpes simplex viruses were not affected. Further evidence for virus specificity was obtained by absorption experiments. For this purpose, sensitised cells were cultured on fixed monolayers of MDV-infected kidney cells or of normal cells. Lymphocytes recovered from normal cell monolayers were still active in plaque inhibition tests whereas those recovered from MDV-infected monolayers were no longer capable of inhibiting plaques (Table 1).

Since sensitised cells were removed by absorption to infected but not to uninfected kidney cell monolayers, it is concluded that plaque inhibition is virus-specific. It follows also that the cells which participate in plaque inhibition are normally non-adherent and that they comprise not more than 1–2% of the population of sensitised cells (Table 1).

The antigens which interact with sensitised cells have not been characterised here, but it is likely that at least some of them might be hitherto unrecognised antigens not detectable using convalescent Marek's disease serum. This follows indirectly from the fact that although Marek's disease serum reacts with antigens at the surface of MDV-infected kidney cells in immunofluorescence tests (17% were positive, Fig. 1*a*), it does not react with infected leukocytes or with infected leukocytes which have been cultured for 24 h. Yet, infected leukocytes could be prevented from forming plaques after a relatively short time of contact with sensitised cells, and the inhibitory effect was abolished by absorbing sensitised cells to MDV-infected kidney cells. It is possible that some of the antigens which act as targets on MDV-infected leukocytes are analogous to cell surface antigens reported in non-producer EBV positive cell lines of Burkitt's lymphoma[6]. Such cells could be lysed by sensitised T lymphocytes although they did not express serologically detectable cell surface antigens.

To determine the nature of the effector cells which operate in plaque inhibition, sensitised cells were pretreated with antisera specific for chicken T and B cells, and their effect on plaque formation estimated. Significant reduction in the capacity of sensitised cells to inhibit plaques was noted only when they were pretreated with anti-T serum and complement (Table 2). As the anti-T and anti-B sera have been shown to be cytotoxic predominantly for homologous cells by the trypan blue exclusion test, it is concluded that plaque inhibition is mediated by T cells.

Table 2 Effect of anti-T serum on the capacity of sensitised cells to inhibit plaque formation

Treatment	Experiment 1 Monolayer infected with kidney cell-associated MDV	Experiment 2 Monolayer infected with leukocyte-associated MDV
Sensitised lymphocytes		
+anti-T+complement	80±3.2*	150±20.1*
+complement	61±2.3	69± 3.0
+normal rabbit serum +complement	65±5.1	75±4.0
+anti-B+complement	54±3.7	91±10.4
+anti-chick Ig +complement	68±4.3	75± 8.3
+anti-T+anti-chick Ig +complement	85±2.6*	141.5±14.9*
Sensitised lymphocytes	60±5	70±8.2
Untreated	80±4.6	160±10.2

Sensitised lymphocytes obtained 50 d after immunisation were treated at a concentration of 5×10^7 per ml with antiserum and complement[10]. Antisera against chicken thymus cells (anti-T) and against chicken bursal cells (anti-B) were obtained from rabbits immunised with T and B cells[11]. Anti-chick Ig was obtained commercially (Nordic). All antisera were used at a final dilution of 1/10. Guinea pig serum absorbed to agarose was used at a final dilution of 1/10 as a source of complement. Treated and untreated sensitised cells were washed twice in RPMI medium +10% foetal calf serum before use in plaque inhibition tests. These were carried out as described for Fig. 1*b* with the exception that monolayers were grown in 30-mm dishes and 3×10^6 sensitised cells were used for each dish. Values (means±s.e.) of plaque counts using lymphocytes from four different birds. Analysis of variance using orthogonal contrast to find the difference between treatment means showed that only treatment with anti-T serum abrogated the capacity of sensitised cells to inhibit plaques.

$*P < 0.001$.

The mechanism of plaque inhibition reported here is different from that reported by others for herpes simplex[7], infectious bovine rhinotracheitis[8] and for varicella–zoster[9] viruses. For these cases, plaque inhibition was attributed to interferon released either as a result of interaction between sensitised peritoneal macrophages and antigen or between sensitised lymphocytes, monocytes and antigen. I was unable to detect interferon-like substances in the medium obtained from cultures in which inhibition of MDV plaques had occurred. Plaque formation by herpes simplex

Table 1 Specificity of plaque inhibition: effect of absorbing sensitised cells to MDV-infected monolayers

	Experiment 1				Experiment 2			
Effector cells	Absorbed to normal cells		Absorbed to MDV-infected cells		Absorbed to normal cells		Absorbed to MDV-infected cells	
Control	140±10	*	124±4	NS	281±9	*	269±19	NS
MDV-sensitised	72±3		128±10		189±4.5		237±17	

Monolayers of normal kidney cells derived from Line 7 birds and of cells heavily infected with kidney cell-associated MDV were fixed with 0.1% glutaraldehyde in phosphate-buffered saline (PBS) for 30 min at room remperature and were thoroughly washed with PBS. Approximately 5×10^7 viable lymphocytes obtained from control birds or from immunised birds 40 d after immunisation were added to the monolayers in 50-mm Petri dishes and were incubated for 3 d at 37 °C in RPMI medium (Flow Laboratories)+10% foetal calf serum. Non-adherent lymphocytes obtained from the medium and by washing the monolayers once were pooled, washed, and used for plaque inhibition. The proportions of the original number of viable lymphocytes plated recovered from monolayers of normal cells were: 7% (control) and 7.2% (MDV-sensitised). Corresponding values for recovery from MDV-infected monolayers were: 6% (control) and 4.8% (MDV-sensitised). Differences in recovery were not significant except in the case of MDV-sensitised lymphocytes cultured on MDV-infected monolayers (the mean reduction in recovery of 1.2% compared with absorption to normal cells was significant, $P < 0.05$ for both experiments). Plaque inhibition tests were carried out as described for Fig. 1 using 5×10^6 sensitised or control lymphocytes as effector cells. Targets in experiment 1 were monolayers preinfected with leucocyte-associated MDV. In experiment 2, leukocyte-associated MDV targets were mixed with effector cells and were plated for infective centres as described for Fig. 1*a*. Values are means±s.e. of plaque counts of four estimations using lymphocytes from four birds for each treatment.

$*0.01 < P < 0.05$.

NS, not significant (Student's *t* test).

was not inhibited when herpes simplex-infected cells, MDV-infected cells and MDV-sensitised lymphocytes were plated simultaneously for infective centres. Similar results were obtained using vaccinia-infected cells (unpublished). Moreover, the cells which participate in plaque inhibition are non-adherent and therefore not macrophages.

Several conclusions can be drawn from these experiments. First, sensitised T cells act independently to inhibit plaque formation. Second, inhibition is probably due to direct lethal interaction between sensitised cells and MDV-infected target cells. Third, hitherto unrecognised virus-specific antigens present at the surface of infected leukocytes may act as targets for sensitised lymphocytes. The plaque inhibition test reported here should prove a better *in vitro* measure of protective immunity than conventional tests for cell-mediated immunity since there is evidence that leukocyte-associated viraemia is invariably reduced in immunised birds compared with controls on infection with virulent MDV (refs 3, 12). A mechanism similar to that reported here for plaque reduction may thus operate *in vivo* to eliminate infected leukocytes and the spread of MDV throughout the tissues of infected birds.

I thank Mr Brian Whitby for technical assistance, Dr P. K. Pani for carrying out some of the statistical tests and Mr M. Rennie and Dr L. N. Payne for supplying anti-T and anti-B antisera.

Heterospecific cytotoxic cell activity induced during the first three days of acute lymphocytic choriomeningitis virus infection in mice

ACUTE infection of adult mice with lymphocytic choriomeningitis virus (LCMV) induces several types of immune responses. H-2-restricted virus-specific cytotoxic T cells are demonstratable from day 5 to 6 and peak on day 7 to 10 post-infection[1–5]. Antiviral antibody in immune complexes is first detected by 4 d post infection[6,7], and non-specifically activated macrophages can be demonstrated after 4 to 5 d (refs 3 and 8). We report here that the acute LCMV infection elicits the production or activation of another type of cytotoxic cell as early as 1 d post infection. These early cytotoxic cells lyse infected or uninfected syngenetic, allogeneic, and xenogeneic cell lines with some specificity. These effector cells do not belong to the cell types thus far implicated in the immune response to LCMV infection and have many of the properties of natural killer cells.

C3H/St (H-2^k) mice were infected intraperitoneally with 2×10^4 plaque forming units (PFU) of the Armstrong strain of LCMV at various days. Their spleens were tested in one test for spleen cell killing of uninfected or LCMV-infected L-929 cells (H-2^k). Figure 1 shows that as early as one day post infection and peaking on the third day post-infection, spleen cells killed uninfected and infected L cell targets with equal efficiency. By the fifth and sixth day post infection, the virus-infected cells were lysed with much greater efficiency than uninfected cells, probably by cytotoxic T cells. During the first 4 d post infection, comparable killing efficiency on a cell-to-cell basis was obtained when peritoneal cells were used as the effector cells. Most subsequent experiments used cytotoxic cells isolated from the spleen or peritoneal fluid of mice at 3 d post infection. Exposure of the LCMV preparation to ultraviolet irradiation[9] before infection of mice abolished its ability to induce the early cytotoxic cells, and the culture fluid of L cells (used to propagate LCMV) did not elicit the killer cell response. Although most ^{51}Cr release assays were run for 16 h, slightly more than 50% of the killing activity occurred during the first 4 h (Table 1*a*). No early cytotoxic cell killing was observed if spleen cells were first incubated overnight at 37 °C before exposure to labelled targets (Table 1*b*). In contrast, the later virus-specific day 8–10 T-cell killing was not reduced by overnight incubation, indicating that the early cytotoxic cells were less stable to *in vitro* incubation than T cells.

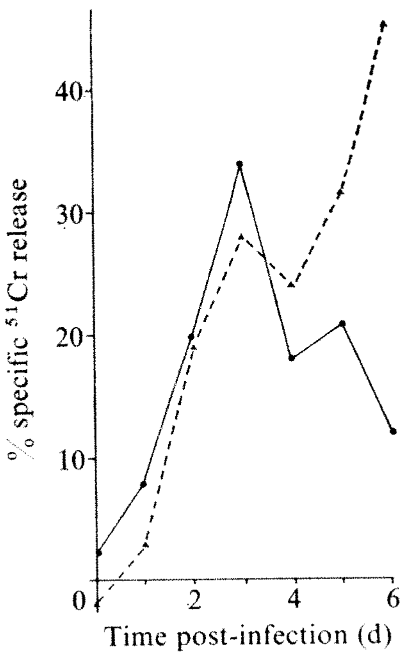

Fig. 1 C3H/St mice were infected intraperitoneally with 2×10^4 PFU of Armstrong strain LCMV. At daily intervals post infection the spleens were collected and cells liberated by gentle squeezing with forceps. Erythrocytes were lysed by exposure to 0.83% NH_4Cl. The erythrocyte-depleted spleen cells were then exposed to 10^4 ^{51}Cr (New England Nuclear) labelled L cells, either uninfected or persistently infected with LCMV[23]. In a total volume of 200 µl in microtitre wells (Falcon no. 3040), spleen cells were added at various effector-to-target ratios (100: 1, 50: 1, 25: 1). Data expressed are at effector-target ratios of 100: 1. Samples were incubated for 16 h before collecting cells. Background release of ^{51}Cr was that obtained with cells incubated under Eagle's minimal essential medium (MEM). Maximum lysis was determined by exposing labelled cells to 1% NP40. Per cent specific ^{51}Cr release was calculated as

$$\frac{(\text{c.p.m. test sample}-\text{c.p.m. MEM control})}{(\text{c.p.m. NP40 control}-\text{c.p.m. MEM control})}\times100$$

All assays were run in quintuplicate, and the standard error of this assay method was < 5% of the mean. The zero time samples represent spleen cell killing from uninfected mice. The values given here and on subsequent tables represent the average of the mean. ●, L cell target; ▲, L(LCMV) cell targets.

The early cytotoxic cells killed a wide variety of cultured syngeneic, allogeneic, and xenogeneic cells. Usually 15–45% of the target cells were killed within 16 h at effector-to-target cell ratios of 100: 1. Spleen cells from

C3H/St (H-2^{k}) mice killed L-929 (H-2^{k}), EL-4 (H-2^{b}), P815 (H-2^{d}), J774 (H-2^{d}), and SCRF 179 lymphoblast (H-2^{z}) mouse cell lines, as well as F-9 cells, which have no detectable H-2 antigens[10]. They also killed continuous primate cell lines (HeLa, Raji, Wil-2, and Vero), as well as early passage mouse (C3H/St and NIH Swiss), rat (BN and Lewis), hamster (Syrian)and human fibroblasts. In contrast, they did not kill freshly harvested unstimulated peritoneal macrophages or splenic lymphocytes from C3H/St mice. The ability of the early cytotoxic cells to kill such a heterogeneous variety of cultured cells suggested nonspecificity, but cold target blocking experiments indicated some degree of specificity (Table 2). Three mouse cell lines with different H-2 specificities and one human cell line (Raji) were exposed to the early cytotoxic cells, and all were lysed at significant levels above controls. Unlabelled cells of each type were then added to the assay wells in sixfold excess of the labelled targets. In all combinations, unlabelled target cells competed best with labelled homologous targets. Nonhomologous cells partially blocked the cytotoxicity to various degrees, suggesting some shared target cell specificity.

Table 1 Stability of early cytotoxic cells in culture % specific ^{51}Cr release

Experiment *a* Duration of assay on L cells (h)

	1	4	8	12	24
Day 3 effector cells	4.5	18	22	21	23
Control effector cells	−1.0	−1.5	3.0	−0.5	2.5

Experiment *b* Cytotoxic activity following incubation in culture

Time of assay after collecting spleen cells (h)	Target	Day of spleen cell harvest 2	4	8	10
0–16	L	16	21	8.8	−0.5
22–38	L	−2.4	−3.4	8.5	1.0
0–16	L(LCMV)	21	29	50	29
22–38	L(LCMV)	−1.3	0.0	64	30

Cells from C3H/St mice taken at the designated times after infection were tested at effector–target ratios of 100 for cytotoxic activity either immediately after harvest (experiment *a*, *b* 0–16), or after overnight incubation (experiment *b* 22–38).

Early cytotoxic cells were detected after acute LCMV infection in both male and female mice of the following strains: AKR, BALB/c, B10.Br, B10.D$_2$, CBA/N × DBA/2 F$_1$, C3H/HeJ, C3H/St, C3H/St × DBA/2 F$_1$, NZB × NZW F$_1$ and athymic nude (BALB/c) mice. The latter result with nude mice suggested that the early cytotoxic cell was not a T cell, and this was confirmed by our findings from four experiments that depletion of spleen T cells with antibody to θ antigen plus complement failed to remove the cytolytic activity (Table 3*a*). Whereas the cytolytic activity of day 8 (T) cells on LCMV-infected syngenetic targets was reduced by 78%, the activity of the day 3 early cytotoxic cells on uninfected targets was enhanced.

Table 2 Specificity of early cytotoxic cell % specific ^{51}Cr release

Effector cell	Blocking cell	Targets EL4*	L929	P815	Raji
Control	None	17	0	1.5	1.5
LCMV	None	44	19	17	25
LCMV	EL4	10	13	11	7.5
LCMV	L929	39	2.6	7.6	16
LCMV	P815	30	15	3.0	16
LCMV	Raji	30	8.1	7.6	1.5

Early cytotoxic spleen cells from C3H/St mice were exposed to ^{51}Cr labelled cell targets at an effector to target ratio of 100. Unlabelled target cells in sixfold excess of the labelled targets were incubated with the labelled targets in some of the reactions (blocking cell). Spleen cells from uninfected control mice were also tested for their cytolytic activity.

*These EL-4 cells express oncornavirus antigens on their cytoplasmic membranes.

Further analyses indicated that the early cytotoxic cell was neither a macrophage nor a polymorphonuclear leukocyte (PML). Most of the cytolytic activity of peritoneal cells isolated from either C3H/St or nude (BALB/c) mice was associated with the non-adherent population (Table 3*b*) after adsorption to plastic. In three other similar adsorption experiments with spleen cells, the killing activity on a cell-to-cell basis was enriched by 5–25% following removal of adherent cells. When macrophages and PML were removed by passing spleen cells through a glass wool column, the effluent cells, which contained <1% macrophages and <2% PML, retained all of their cytolytic activtiy.

We found that during the first 3 d after LCMV infection in adult mice, cytotoxic cells appear that kill many types of uninfected or infected cultured cells with some specificity but do not kill primary macrophages or lymphocytes. Pfizenmaier *et al.*[4,5] have reported that 5 d after infection of mice with LCMV, cytotoxic T cells are generated which kill both infected and uninfected syngeneic targets, and Blanden and Gardner[11] have described the appearance of early killer T cells that lysed uninfected syngeneic targets 2–4 d after infection of mice with ectromelia virus. Rodda and White[12] reported a possibly similar early killer cell during Semliki Forest virus infection of mice but concluded that it was a macrophage. The early cytotoxic cell that we describe here is clearly neither a T cell nor a macrophage nor a PML. Cytotoxic cells which are labile at 37 °C and kill tumour cells but not primary cell lines have been reported and designated natural killer (NK) cells. These cells lack surface antigen markers (IgG, Fc receptors, C3 receptors, θ antigen) and lyse Moloney leukaemia/sarcoma virus infected or transformed cell targets[13-17]. The LCMV infection may activate normally undetectable NK cells that have some additional target specificities. A similar induction of NK cell activity in mice can be elicited by Bacille Calmette-Guerin (BCG) (ref. 18). An alternative hypothesis is that the LCMV infection may induce a polyclonal natural antibody response which would mediate antibody-dependent cell cytotoxicity (ADCC) by K cells, cytolytic lymphocytes with Fc receptors[19,20].

Table 3 Characterisation of early cytotoxic cells % specific ^{51}Cr release

Experiment *a* Depletion of spleen T cells*

Effector cell	Target cell	Treatment of effector cell None	Anti-θ + C	C
Day 3	L	10	13	9.3
Day 8	L(LCMV)	63	14	62

Experiment *b* Adherence properties of peritoneal killer cells†

Effector cell	C3H/St mouse	Nude (BALB/c) mouse
Day 3 non-adherent	17.4	22.2
Day 3 adherent	5.5	5.8
Day 3 unseparated	18.5	26.6
Control unseparated	0.4	0.5

*Spleen cells from days 3 or 8 post infection were treated with antibody to θ antigen (a gift from R. Blanden) and guinea pig complement (C), which had previously been absorbed against C3H/St mouse spleen cells. After incubation, the spleen cells were washed and tested on labelled L or L(LCMV) targets at an effector–target ratio of 50.

†Peritoneal cells were adhered to plastic microtitre wells for 2 h at a concentration of 5×10^{5} cells per well (effector–target ratio = 50). The non-adherent cells were gently pipetted off the monolayers and transferred to other wells without adjusting the cell number. A monolayer of adherent cells (> 80% macrophages) was left. Target L cells were added to the wells for a ^{51}Cr release assay.

Epstein–Barr virus has been reported to induce polyclonal B-cell activation of cultured human lymphotcytes[21]. We have been unable to establish a functional role for immunoglobulins or Fc receptors in our system, and little activity is associated with populations of adherent cells (Table 3), known to be effectors of ADCC in mice[22]. This phenomenon cannot be explained by the transfer of virus with the spleen cells to the labelled targets, rendering them sensitive to anti-LCMV ADCC because (1) there is some target cell specificity, (2) most killing occurs at a time (4 h) before the viral antigens could be expressed on the surface of infected target cells, (3) Raji cells are sensitive targets yet refractory to LCMV infection (R.M.W., unpublished), and (4) very little virus infectivity is transferred in macrophage depleted spleen cell populations. Thus, although we cannot yet completely exclude an ADCC mechanism, our data describing a heat labile, non adherent, non-T lymphocyte active against a variety of cell targets in the absence of added antibody suggest that the early cytotoxic cell generated during the first few days of the LCMV infection is similar to an NK cell.

This work was suported by USPHS grants AI 12438, AI 13779, AI 07007 and NS 12428. We thank Dr Michael Oldstone for support of this project and review of the manuscript and Alana Althage and Linda Hallenbeck for technical assistance.

Note added in proof: Inductions of NK-like cells in mice by acute virus infections have recently been observed by several other laboratories[24–26].

Protein covalently linked to foot-and-mouth disease virus RNA

THE RNA in picornaviruses can function directly as mRNA (ref. 1). In contrast to the great majority of cellular and virus mRNA molecules, however, a 'cap' structure has not been found at the 5′-end of the RNAs of polio[2,3] and encephalomyocarditis (EMC) (ref. 4) virus particles or on poliovirus specific mRNA in infected cells[2,3]. The 5′-terminus of poliovirus mRNA extracted from polyribosomes was found to be pUp[2,3] but no nucleotide could be identified at the 5′-end of the RNA in virus particles. This is because a small protein is covalently linked to the 5′-terminal nucleotide of the RNA (refs 5, 6). The RNAs of EMC virus and foot-and-mouth disease virus (FMDV) contain a tract of about 100–200 cytidylic acid residues located near the 5′-end[7,8] but such a sequence was not found in poliovirus RNA (ref. 9). It was of interest, therefore, to determine whether a protein is also covalently linked to FMDV RNA and whether it is attached to the poly C tract. We show here that FMDV RNA is not capped and demonstrate the presence of a protein of molecular weight (MW) about 4,000 covalently linked to the RNA. The protein is not attached directly to the poly C tract but is probably attached to the 5′-terminus and can be removed without loss of infectivity.

When FMDV particles labelled with ^{3}H-uridine and ^{35}S-methionine were extracted with phenol–chloroform in the presence of sodium dodecyl sulphate (SDS), about 0.03% of the ^{35}S counts remained in the aqueous phase together with all the ^{3}H-labelled RNA and could not be removed by repeated extractions with phenol–chloroform. After sedimentation through a sucrose density gradient containing 0.1% SDS, the ^{35}S counts coincided with the ^{3}H-labelled peak of RNA (Fig. 1*a*). The ^{35}S counts were still associated with the RNA after heating at 70 °C for 1 min in 100% formamide (Fig. 1*b*), or at 100 °C for 1 min in 5% SDS, 5% mercaptoethanol and 2.5 M urea (Fig. 1*c*), conditions which would be expected to disrupt non-covalent bonds between protein and RNA. The altered sedimentation profile of the RNA after heating at 100 °C (Fig. 1*c*) is probably due to non-random degradation.

In contrast, treatment with Pronase in the presence of 0.1% SDS completely removed the ^{35}S-labelled material from the RNA without altering its sedimentation profile (Fig. 1*d*). These results strongly suggest that the ^{35}S-labelled material is covalently attached to the RNA and is a protein. No ^{35}S-labelled material was associated with the RNA of virus grown in pre-labelled cells, suggesting that the protein is not host specific. Further evidence that the protein and RNA are linked covalently was obtained by digestion with a mixture of T_1 and pancreatic ribonucleases. After this treatment the ^{35}S material remained at the top of a sucrose density gradient demonstrating that it was not fortuitously sedimenting at a rate similar to that of the RNA. The protein is not required for infectivity since an ^{35}S-methionine labelled FMDV RNA preparation with a titre of 1.7×10^6 placque-forming units per ml and containing 266 c.p.m. per ml had the same titre and sedimentation rate but contained less than 7 c.p,m, per ml after Pronase treatment. This result is in accord with the observation that poliovirus particle and mRNAs have similar specific infectivities despite the lack of a 5′-linked protein on the mRNA (ref. 15).

To characterise the protein the RNA isolated from ^{35}S-methionine labelled FMDV was purified by sucrose gradient centrifugation and then analysed by electrophoresis on 20% polyacrylamide gels[11] with or without digestion with a mixture of T_1, T_2 and pancreatic ribonucleases. All the ^{35}S counts in the untreated material remained at the top of the gel but after digestion with the ribonucleases the ^{35}S-labelled material migrated as a band with an apparent MW of about 4,000. Co-electrophoresis of the FMDV RNA-linked protein labelled with ^{35}S-methionine and the corresponding protein from poliovirus labelled with ^{3}H-lysine on high cross-linked polyacrylamide gels[12] showed that they had similar molecular weights.

The 5′-end of the virus RNA was shown to be blocked by analysis of the nucleotides produced by digestion of ^{32}P-labelled RNA with a mixture of T_1, T_2 and pancreatic

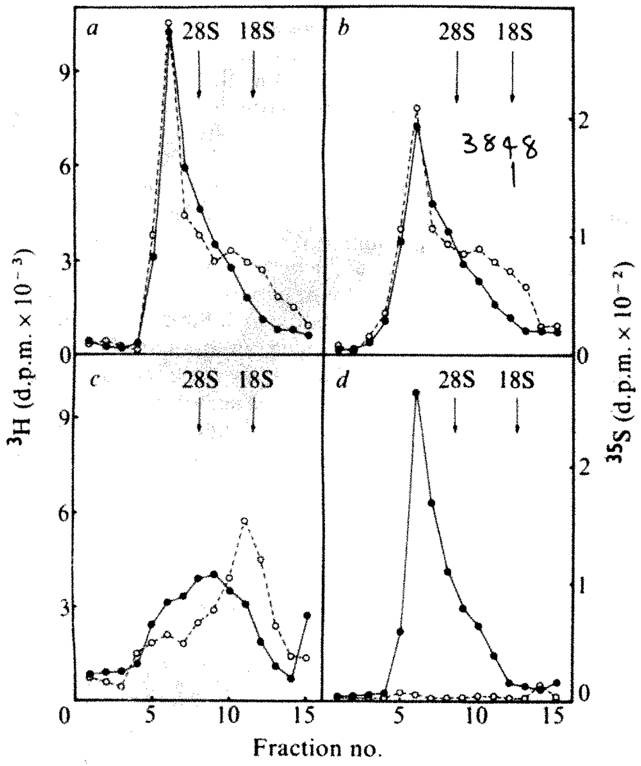

Fig. 1 Effect of denaturing conditions and Pronase on the sedimentation of FMDV RNA. The virus, type A61, was grown in the presence of ^{3}H-uridine (0.2 μ Ci ml^{-1}) and ^{35}S-methionine (25 μ Ci ml^{-1}, Radiochemical Centre, Amersham) and purified by sucrose gradient centrifugation[10]. The RNA was extracted with phenol–chloroform–SDS and precipitated at −20 °C with ethanol. Aliquots of the precipitated RNA were dried under N_2 and treated as follows before centrifuging at 50,000*g* for 16 h at 20 °C through 5–25% sucrose gradients in 0.1 M acetate –0.1% SDS, *p*H 5.0. The RNA was dissolved in *a*, 0.5 ml TNE–SDS (0.1 M Tris, 0.1 M NaCl, 0.001 M EDTA, 0.1% SDS, *p*H 7.5) and heated at 37 °C for 1 h; *b*, 0.1 ml 100% formamide and heated at 70 °C for 1 min before diluting to 0.5 ml with TNE–SDS; *c*, 0.1 ml disrupting solution (2.5 M urea, 5% mercaptoethanol, 5% SDS) and heated at 100 °C for 1 min before diluting to 0.5 ml with TNE–SDS; *d*, 0.5 ml TNE–SDS containing 50 μg Pronase and heated at 37 °C for 1 h. BHK ribosomal RNA was then added to each sample to serve as marker before centrifugation. Each fraction was precipitated with 10% TCA in the presence of bovine serum albumin (BSA) and filtered on to a glass fibre disk before counting in a liquid scintillation counter. ●, ^{3}H; ○, ^{35}S.

ribonucleases. Chromatography of the digest on DEAE–Sephadex in the presence of 7 M urea showed that there were no nucleotides eluting with a net charge expected for a nucleotide tetraphosphate (−6) or a capping group (−5 to −6) or a structure of the type pXp (−4) or ppXp (−5). This result is consistent with the presence of a free OH or a blocked structure at the 5′-end of the RNA in virus particles.

Further evidence that the 5′-end of the virus RNA was blocked was provided by electrophoresis on Whatman 3MM paper at *p*H 3.5 of the nucleotides produced by complete ribonuclease digestion. Four mononucleotide peaks were obtained together with small amounts of inorganic phosphate and cyclic mononucleotides, but in addition approximately 0.016% of the ^{32}P migrated towards the cathode. In contrast, less than 0.006% of the ^{32}P moved towards the cathode when the RNA was treated with Pronase before ribonuclease digestion. This suggests that a protein is attached to the 5′-end of FMDV-RNA in the same way that a protein is linked to poliovirus RNA[6].

As our previous work[8] had shown that the polyC tract in FMDV RNA is located near the 5′-end it seemed possible that the protein was attached to the polyC tract. To test this possibility the RNA prepared from FMDV labelled with ^{35}S-methionine and ^{3}H-cytidine was digested with ribonuclease T_1 and the oligonucleotide products separated by electrophoresis on a 12.5% polyacrylamide gel in 6 M urea at *p*H 8.5. The ^{35}S-methionine peak did not coincide with the ^{3}H-cytidine labelled polyC tract (Fig 2*a*) indicating that the protein was not attached to it directly. After T_1 and pancreatic ribonuclease digestion of ^{35}S-methionine-labelled RNA and subsequent electrophoresis on a similar gel all the radioactivity was found near the top of the gel (Fig. 2*b*), indicating that the protein does not move to the position shown in Fig. 2*a* because of its intrinsic size and charge at *p*H 8.5.

An important feature of the replication of FMDV is that less than 20% of the single stranded (ss) RNA synthesised in infected cells is encapsulated into virus particles[13]. Furthermore, the intracellular FMDV specific ssRNA sediments as a broad band in sucrose gradients with a peak at about 37S, whereas RNA extracted from virus particles sediments at 35S. The amount of protein associated with intracellular FMDV induced ssRNA was found to alter during the growth cycle. Only low levels of ^{35}S labelling were found on RNA up to the time when about half of the total RNA had been synthesised. Thereafter a greater proportion of ^{35}S labelling was observed and this continued to increase after RNA synthesis had virtually ceased. The

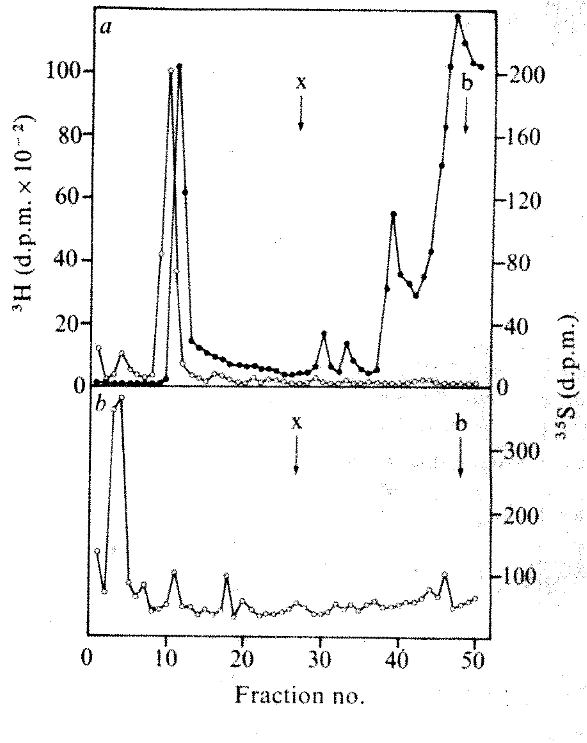

Fig. 2 Polyacrylamide gel electrophoresis of FMDV RNA after digestion with ribonuclease T1 or a mixture of T1 and pancreatic ribonucleases: *a*, Separate preparations of FMDV RNA labelled with either ^{3}H-cytidine or ^{35}S-methionine were prepared as described under Fig. 1 and purified further by centrifugation on 5–25% sucrose gradients in 0.1 M acetate–0.1% SDS, *p*H 5.0 at 20 °C for 18 h at 50,000*g*. The fractions containing the peak of RNA at about 35S were precipitated with ethanol in the presence of 100 μg *Escherichia coli* tRNA as carrier and digested with 30 units of ribonuclease T1 in 20 μl 0.01 M Tris-HCl 0.001 M EDTA containing 10 μg BSA for 1 h at 37 °C. *b*, 25 μg pancreatic ribonuclease added to the digestion mixture. The digested samples were mixed with an equal volume of dye marker (0.2% xylene cyanol (x), 0.2% bromophenol blue (b) in 50% sucrose, 6 M urea) and loaded on to 10 × 0.6-cm cylindrical 12.5% polyacrylamide gels made in 0.1 M Tris-borate, 0.0025 M EDTA, 6.0 M urea, *p*H 8.3 and subjected to electrophoresis for about 3 h at 100–150 V when the bromophenol blue had migrated 9 cm. The gels were sliced into 1.5-mm segments, digested with 0.5 ml NCS and the radioactivity determined by liquid scintillation counting in a toluene-based scintillation fluid, using appropriate spill-over corrections. ●, ^{3}H; ○, ^{35}S.

protein was associated with the entire heterogeneous induced ssRNA peak and not just with the 35S virus particle RNA.

We conclude from these observations that the ^{35}S-labelled material associated with the RNA extracted from ^{35}S-methionine-labelled FMDV particles is a protein of MW about 4,000 and is attached covalently. Our results are similar to those reported for poliovirus RNA (refs 5, 6). The protein linked to the RNA of poliovirus does not contain methionine[5] but that attached to the RNA of FMDV contains at least one methionine residue. If it is assumed that the protein in FMDV contains only one residue of methionine then the proportion of radioactivity in virus particles associated with the RNA-linked protein is compatible with the presence of a single copy in each virus particle.

The absence of a cap structure or an identifiable 5′ end on FMDV-RNA supports the hypothesis that, as with poliovirus RNA, a protein blocks the 5′ end of the RNA. The fact that the protein does not seem to be attached to the polyC tract suggests that this homopolymer is not 5′-terminal. The association of the protein with ssRNA parallels the appearance of mature virus particles in the cells and it is tempting to speculate that the protein has a regulatory role in determining whether the RNA is incorporated into virus particles as Fernandez-Munoz and Lavi have suggested for poliovirus[14]. The covalently-linked protein of poliovirus RNA has been found in replicative intermediate RNA (ref. 6) and on the 5′ end of negative RNA strands[15], leading to the suggestion that the protein has a role in transcription, acting as a primer on the nascent RNA strands and being cleaved from the RNA destined to become polysomal mRNA. A more detailed analysis of the fate of the RNA synthesised at different times after infection and an examination of the protein linked to the replicative intermediate should help to elucidate the role of the protein in virus replication.

Participation of DNA-dependent RNA polymerase II in replication of influenza viruses

FOR many years it has been known that inhibitors of the expression of cell DNA, such as actinomycin D, prevent the multiplication of influenza viruses; inhibitors of DNA synthesis have no such effect[1–3]. This phenomenon is still not understood, even though from the outset the available data have suggested that cell gene transcription may be a necessary prerequisite for virus RNA transcription and replication[2]. The discovery that α-amanitin, a specific inhibitor of nucleoplasmic DNA-dependent RNA polymerase II (ref. 4), also specifically inhibits influenza virus replication[5,6], is additional support for the theory that cell gene expression is essential for virus growth. There has always been the possibility, however, that inhibition of virus growth is unrelated to the defined activities of DNA function inhibitors. It is possible, for example, that actinomycin D or α-amanitin might prevent the uptake or uncoating of influenza viruses, might inhibit directly the virion-associated transcriptase *in vivo*, or might act in some other unrecognised way. We describe here experiments in which α-amanitin was tested for its ability to inhibit the growth of influenza virus in cells containing an α-amanitin-resistant DNA-dependent RNA polymerase; in these circumstances, the virus grows normally in the presence of high concentrations of α-amanitin. This finding indicates that DNA-dependent RNA polymerase II has an essential role in the replication of influenza viruses.

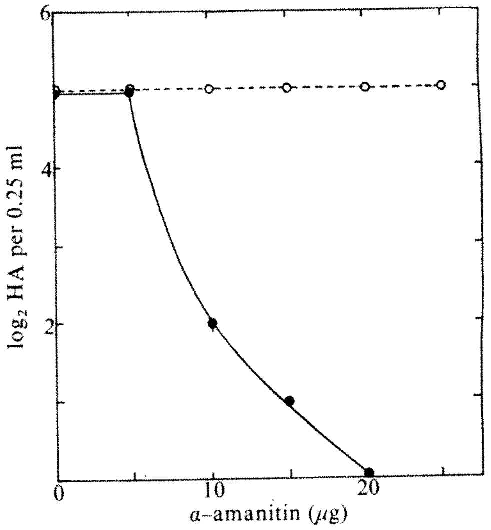

Fig. 1 Effect of increasing doses of α-amanitin on the yield of FPV from α-amanitin-sensitive, wild-type (●) and α-amanitin-resistant, mutant AMA-1 (○) CHO cells. Confluent monolayer cultures of cells were pre-incubated in medium containing α-amanitin for 1 h before infection with FPV (10 p.f.u. per cell), and α-amanitin was present in the culture medium throughout the experiment. At 24 h the amount of virus released into the medium was determined using an HA assay. Similar results were obtained when infected cells were disintegrated by Dounce homogenisation before HA determination.

The experiments were carried out on Chinese hamster ovary (CHO) cells infected with the avian influenza A virus, fowl plague (FPV). Two cell lines were kindly provided by Dr L. Siminovitch, University of Toronto, Canada, comprising the normal, α-amanitin-sensitive, wild-type CHO cell, and the mutant, α-amanitin-resistant (AMA-1) line. AMA-1 cells contain an α-amanitin-resistant DNA-dependent RNA polymerase II (refs 7–9). Cells were grown as monolayers in small plastic flasks in Dulbecco's MEM medium containing 10% foetal calf serum. For virus infection, cell sheets were washed with PBS, and allantoic fluid containing FPV was added to provide a multiplicity of infection of 10 PFU per cell. After 30 min adsorption, fresh MEM medium containing 2% foetal calf serum was added to the cells. Viral growth occurred in both cell types, and newly synthesised virus was detected either by haemagglutinin (HA) or plaque assay; maximum yields were obtained by 12 h after infection. The effects of increasing doses of α-amanitin in the culture medium on the 24-h yields of FPV from wild-type and AMA-1 cells, as determined using the HA assay, are shown in Fig. 1. Similar results were obtained when yields were measured by plaque assay. A dose-dependent inhibition of virus yield was observed only in wild-type cells. α-Amanitin (20 μg ml^{-1}) in the culture medium produced >95% reduction in the yield of influenza virus from wild-type CHO cells, but had no effect on the yield of virus from AMA-1 cells. These results indicate that the growth and release of influenza virus in AMA-1 cells is unsusceptible to α-amanitin.

To confirm that the DNA-dependent RNA polymerase II of AMA-1 cells is resistant to α-amanitin, in both uninfected and infected cells, the effect of α-amanitin on enzyme activity in isolated cell nuclei was determined. The polymerase II activity of nuclei extracted from uninfected wild-type and AMA-1 cells, both in the presence and absence of α-amanitin (5 μg ml^{-1}) was determined using the method of Lobban and Siminovitch[8]. A similar experiment was carried out using nuclei from both cell types infected 1 h previously with FPV, and the results are shown in Table 1. α-Amanitin reduced polymerase activity of both uninfected and infected wild-type CHO cells by 70–75%. The drug had no effect on polymerase levels of uninfected and infected AMA-1 cells. Virus infection seemed to increase enzyme activity by 20–30% at 1 h after infection.

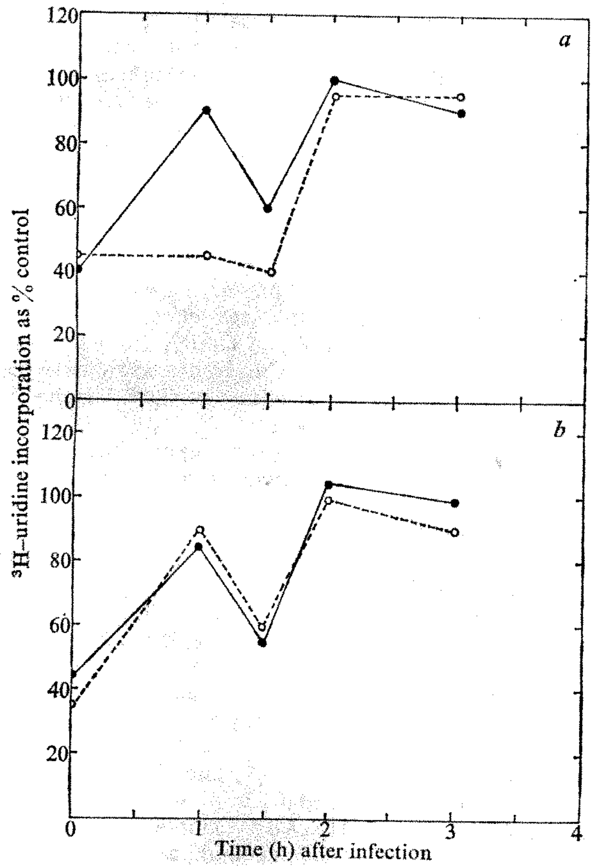

Fig. 2 Effect of α-amanitin on RNA synthesis in FPV-infected CHO cells. Confluent monolayers of wild-type and AMA-1 CHO cells were prepared in small, plastic flasks and infected with FPV at an input multiplicity of 10 PFU per cell. At various times, duplicate infected and control cultures were treated with α-amanitin 20 μg ml^{-1} for 1 h, followed by a 20-min pulse of ^{3}H-uridine (5 μCi ml^{-1}, 27.6 Ci mmol^{-1}). Cells were then washed with TCA and the amount of insoluble radioactivity determined by scintillation counting. The results are expressed as percentage counts incorporated into

$$\frac{\text{α-amanitin-treated FPV-infected CHO cells}}{\text{α-amanitin treated, uninfected cells}} \quad (\bigcirc)$$

and are compared with the percentage counts incorporated into

$$\frac{\text{FPV-infected CHO cells}}{\text{Uninfected cells}} \quad (\bullet)$$

a, Wild-type cells; *b*, AMA-1 cells.

In an attempt to establish the stage of the virus replication cycle affected by α-amanitin, virus-induced RNA synthesis was determined in infected wild-type and AMA-1 cells in the presence and absence of α-amanitin. Infected cells were exposed to an inhibitory dose of α-amanitin at various times following infection, and some time later their ability to synthesise RNA was determined. This experiment was carried out by adding α-amanitin (20 μg ml^{-1}) to the culture medium for 1 h before infection, or for hourly

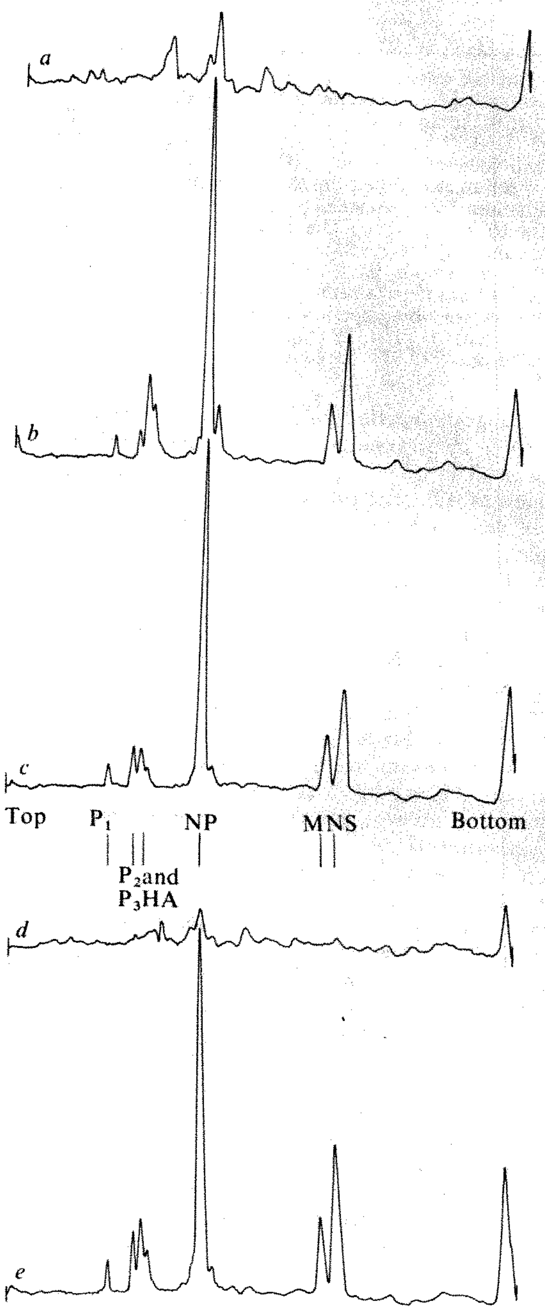

Fig. 3 Polyacrylamide slab gel electrophoresis of ^{35}S-methionine-labelled, high molecular weight polypeptides synthesised by uninfected and FPV-infected CHO cells. *a*, Uninfected wild-type CHO cells; *b*, wild-type CHO cells at 3¼ h after infection by FPV (10 PFU per cell); *c*, infected AMA-1 cells at 3¼ h; *d*, infected wild-type CHO cells at 3¼ h, α-amanitin 20 μg ml^{-1} present in the medium throughout infection; *e*, infected AMA-1 cells at 3¼ h, α-amanitin 20 μg ml^{-1} present in the medium throughout infection. Cells were infected or mock-infected and at 3 h received ^{35}S-methionine 5 μCi ml^{-1} for 15 min, before being processed for electrophoresis[12]. The material was loaded on to a 15% SDS–acrylamide gel, run for 16 h at 50V and processed for autoradiography. Densitometer tracings of the resulting autoradiographs are shown; the direction of migration and location of virus-induced polypeptides is indicated.

	5	103
AMA-1 infected	0	131
	5	127

*Polymerase reaction mixture is based on that described by Lobban and Siminovitch[8]. In a volume of 560 μl were mixed 20 μmol Tris-HCl (*p*H 7.9); 0.7 μmol $MnCl_2$, 37.5 nmol each of ATP, CTP and GTP, 10 μCi ^{3}H-UTP at 40 Ci mmol^{-1} specific activity; 1.1 μmol β-mercaptoethanol; 240 μmol $(NH_4)_2SO_4$, and about 150 μg of purified cell nuclei. When the assay was carried out in the presence of α-amanitin, samples were pre-incubated with 5 μg ml^{-1} of the drug for 10 min at 37 °C. The mixture was then incubated at 30 °C for 15 min, and the reaction was terminated by addition of 1 ml $Na_4P_2O_7$ containing 0.2% bovine serum albumin. Acid-soluble radioactivity was determined by the method of Mahy and Bromley[11].

†Controls for this experiment were wild-type uninfected nuclei (2.36×10^5 c.p.m. ^{3}H-UTP mg^{-1} nuclear protein) and AMA-1-uninfected nuclei (2.57×10^5 c.p.m. mg^{-1}).

intervals from the time of infection and then exposing the cells to a 20-min pulse of ^{3}H-uridine (5 μCi ml^{-1}, 27.6 Ci mmol^{-1}). The level of TCA-insoluble radioactivity thus obtained at different times following infection in the drug-treated cells, was compared with that obtained in infected, untreated cultures. The results are shown in Fig. 2. Two peaks of virus-induced RNA synthesis (early and late) could be detected in both cell lines in the absence of α-amanitin, as has been described previously in FPV-infected primary chick cells[6,10]. AMA-1 cells treated with α-amanitin are indistinguishable from untreated cells, but the presence of α-amanitin inhibits the early peak of virus-induced RNA synthesis in wild-type CHO cells. The results suggest that the α-amanitin-sensitive step, mediated by DNA-dependent polymerase II, occurs early in infection.

To determine whether functional virus mRNA is made in α-amanitin-treated cells, the synthesis of virus polypeptides in infected wild-type and AMA-1 cells was investigated. Both cell types were infected with FPV in the presence or absence of α-amanitin (20 μg ml^{-1}) and at 3 h after infection received ^{35}S-methionine (5 μCi ml^{-1}) for 15 min. The cells were then processed for polyacrylamide gel electrophoresis and autoradiography according to the method described by Inglis *et al.*[12]. Densitometer tracings of the resulting autoradiogram are shown in Fig. 3. α-Amanitin reduced protein synthesis in infected wild-type cells to a level below that seen in uninfected cells. Virus-induced protein synthesis in α-amanitin-treated AMA-1 cells was quantitatively and qualitatively indistinguishable from that in cells untreated with α-amanitin.

The results reported here indicate that transcription of cell DNA by DNA-dependent RNA polymerase II is essential for the replication of influenza viruses. This transcription is an early event, apparently preceding the synthesis of virus-specific mRNA.

Dopamine selectively increases ^{3}H-GABA release from slices of rat substantia nigra *in vitro*

THE firing rate of the dopaminergic neurones in the substantia nigra (s. nigra) of mammalian brain is controlled largely by descending striatonigral neurones. But new evidence suggests that the activity of nigral neurones may also be modulated by local circuits within the s. nigra, involving a local dendritic release of dopamine[2]. The demonstration that dopamine is present in[3], and released[4-6] from, the dendrites of nigral neurones both *in vitro* and *in vivo* supports this concept. The precise site of action of dopamine in the s. nigra is not known, but a dopamine-sensitive adenylate cyclase has been described in this brain region[7], apparently located presynaptically on the terminals of striatonigral afferents[8-10] containing either γ-aminobutyric acid (GABA) or substance P[11,12]. To determine whether presynaptic dopamine receptors in s. nigra are associated with substance P or GABA-containing axon terminals, we have investigated the effects of dopamine on the release of substance P and GABA from superfused slices of rat s. nigra *in vitro*. Our results show that dopamine stimulates selectively the release of GABA from nerve terminals in s. nigra.

Substantia nigra tissue (weighing approximately 6 mg, from one brain) was dissected from 0.8 mm coronal sections of fresh chilled rat brain. Initially the high affinity uptake of ^{3}H-GABA into 0.2×0.2-mm slices of s. nigra was measured, using the method of Iversen and Johnston[13]. After 10 min of incubation with ^{3}H-GABA (10^{-7} M) at 37 °C, a tissue : medium ratio of 72.9 ± 2.1 (mean ± s.e.m.; $n = 4$) was found, indicating that slices of s. nigra accumulated exogenous GABA avidly from the external medium.

Substance P release from superfused nigral slices was measured as described previously[14]. In experiments to measure GABA release, nigral tissue from two rats was pooled, incubated with ^{3}H-GABA, and the release of ^{3}H-GABA was measured in serial 2 min superfusate fractions (Fig. 1). The efflux of ^{3}H-GABA exhibited a rapid initial decline and after 15 min stabilised at a level which represented a loss of 0.7–0.9% of total tissue stores of ^{3}H-GABA per minute. Addition of depolarising concentrations of potassium chloride (11–47 mM) to the superfusing medium for 4 min produced a concentration-dependent release of ^{3}H-GABA. The potassium-evoked release of H-GABA was abolished in media with reduced Ca^{2+} and elevated Mg^{2+} concentrations (Table 1*a*). Okada and Hassler[15] described an electrically-evoked release of GABA from slices of rat s. nigra *in vitro*, but failed to demonstrate the calcium-dependence of this phenomenon.

Addition of dopamine (5–500 μM) to the superfusing medium for 4 min also produced a concentration-dependent increase in the rate of ^{3}H–GABA release. (Fig. 1*a*, Table 1*c*) and this effect was completely abolished in media with reduced Ca^{2+} and elevated Mg^{2+} concentrations. The actions of dopamine in both the corpus striatum and s. nigra

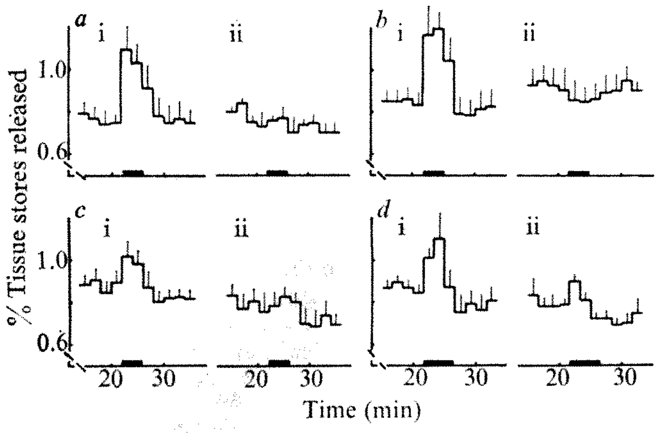

Fig. 1 Release of ^{3}H-GABA from rat substantia nigra. Slices of rat substantia nigra (0.2 × 0.2 mm) were incubated for 20 min in Krebs bicarbonate solution containing 10^{-7} M 3H-GABA (Radiochemical Centre, Amersham; specific activity 12.6 Ci mmol^{-1}). After incubation they were transferred to a superfusion apparatus[4] and washed at 37 °C with Krebs bicarbonate (containing 30 mg l^{-1} ascorbic acid and 10 mg l^{-1} EDTA to inhibit the spontaneous breakdown of added dopamine), at a rate of 0.5 ml per min. Superfusate samples were collected at 2 min intervals and the tritium content was determined. Nigral tissue was recovered at the end of the superfusion and the total content of radioactivity measured. ^{3}H-GABA efflux is expressed as a fractional rate constant, which represents the amount of ^{3}H released per minute in each sample as a percentage of the total tissue content of ^{3}H-GABA. In similar experiments over 90% of the radioactivity recovered in tissue and superfusate fractions was found to represent unchanged ^{3}H-GABA[21]. *a*, i, Release of ^{3}H-GABA evoked by addition of 50 μM dopamine (4 min, black bar, $n = 8$). ii, Effect of 50 μm dopamine in medium containing 0.1 mM Ca^{2+} and 12 mM Mg^{2+} ($n = 4$). *b*, Effect of α-flupenthixol (1 μM) on dopamine-evoked ^{3}H-GABA release. i, 50 μM dopamine pulse (4 min, black bar, $n = 5$). ii, Dopamine 50 μM (4 min) after addition of α-flupenthixol (1 μM) from min 18 to 24 ($n = 5$). *c*, Dexamphetamine-evoked release of ^{3}H-GABA. i, Amphetamine 50 μM (4 min, black bar, $n = 6$). ii, Amphetamine 50 μM after addition of α-flupenthixol (1 μM) for the total period of superfusion ($n = 4$). *d*, Evoked release of ^{3}H-GABA by addition of dibutyryl-cyclic AMP (db cAMP). i, db cAMP (1.2 mM) for 6 min (black bar), $n = 4$. ii, db cAMP (1.2 mM) in medium containing 0.1 mM Ca^{2+} and 12 mM Mg^{2+} ($n = 4$).

are mediated by dopamine receptors linked to a specific dopamine-sensitive adenylate cyclase that is potently antagonised by neuroleptic drugs[7,16,17]. Addition of the neuroleptics α-flupenthixol (1 μM) (Fig. 1*b*) or fluphenazine (1 μM) (Table 1*d*) to the superfusing medium completely abolished the dopamine-evoked release of ^{3}H-GABA. Haloperidol (1 μM) (Table 1*e*) also markedly suppressed the dopamine-evoked release. The potent dopamine agonist 4 - amino,6 - 7 - dihydroxy - 1,2,3,4 - tetrahydronaphthalene (ADTN) (ref. 18) (50 μM) mimicked the stimulatory effect of dopamine on ^{3}H-GABA release (Table 1*f*). The dopamine-evoked release of ^{3}H-GABA in the s. nigra thus seems to be mediated by an action on dopaminergic receptors with pharmacological specificity similar to that of receptors in other dopamine-rich brain areas.

Addition of dexamphetamine (50 μM) also caused a small but significant ($P<0.05$) release of ^{3}H-GABA from slices of s. nigra (Fig. 1*c*), and this effect could be blocked by previous exposure to α-flupenthixol (1μM). Amphetamine lacks any direct action on central nervous system (CNS) dopamine receptors[18], but stimulates a release of tissue stores of dopamine in various regions of CNS including s. nigra[2,19]. The stimulatory effect of amphetamine suggests that a release of endogenous dopamine from the dendrites of nigral neurones can stimulate a local release of GABA. A functional dendro–axonic synaptic interaction may thus exist even in superfused slices of s. nigra maintained *in vitro*.

Superfusion with the stable cyclic AMP analogue, dibutyryl-cyclic AMP (1.2 mM) also caused a calcium-dependent increase in ^{3}H-GABA release (Fig. 1*d*), showing that the effect of dopamine may be related to increases in intracellular cyclic AMP levels in GABA-containing nerve terminals. Minneman and Cuello (personal communication) have observed presynaptic localisation of cyclic nucleotide phosphodiesterase in the rat s. nigra, providing further evidence for the localisation of a cyclic AMP system within nerve terminals in the s. nigra.

Although there is evidence for an involvement of cyclic AMP, the cellular mechanism responsible for the dopamine-evoked release of GABA remains unknown. The calcium dependence of this phenomenon suggests a possible similarity to the mechanism involved in the normal stimulus-evoked release of transmitters. Furthermore, when nigral slices were exposed simultaneously to dopamine (50 μM) and to high potassium (11 mM) the effects on ^{3}H-GABA release were not additive (Table 1*b*). In parallel experiments the spontaneous efflux of substance P was found to be 28.36±4.08 fmol mg^{-1} (mean±s.e.m; $n=4$); addition of dopamine (50 μM) for 4 min produced no significant change in spontaneous efflux (29.84±0.88 fmol mg^{-1}, $n=4$). Similarly the potassium-evoked release of substance P (36.41±4.07 fmol mg^{-1}; $n = 3$) was unaffected by simultaneous addition of dopamine (39.26±6.13 fmol mg^{-1}; $n = 3$).

Since high affinity GABA uptake occurs into glial cells as well as neurones, it is possible that the GABA release we have described occurred partly from glial cells. But, the apparent localisation of dopamine-sensitive adenylate cyclase on striatonigral nerve terminals suggests that dopamine released within the s. nigra produces a selective stimulation of the release of GABA located within inhibitory striatonigral terminals, and this might provide the basis for a local inhibitory feedback circuit. The inhibitory effects of dopamine when applied iontophoretically into the s. nigra[20] may, at least in part, be mediated by such an effect of dopamine on GABA-containing axon terminals. The lack of effect of dopamine on substance P release suggests that the dopamine-sensitive adenylate cyclase in rat s. nigra may be localised predominantly on GABA-containing axon terminals.

ADTN was provided by Dr T. Inch, Chemical Defence Research Establishment, Porton Down, and substance P by Dr R. Hirschmann, Merck, Sharpe and Dohme. T.M.J.

Table 1 Effect of dopamine (DA) and high potassium (K^+) on release of ^{3}H-GABA from rat substantia nigra

Stimulus	Evoked release of ^{3}H-GABA (% of total tissue stores)
a K^+ 11 mM	3.78±0.56 (4)
K^+ 23 mM	5.94±1.02 (4)
K^+ 47 mM	9.70±1.88 (4)
K^+ 11 mM; Ca^{2+} 0.1 mM, Mg^{2+} 12 mM	0.08±0.12 (4)
b K^+ 11 mM + DA 50 μM	3.40±0.62 (4)
c DA 5 μM	1.46±0.38 (5)
DA 50 μM	2.24±0.40 (8)
DA 500 μM	3.00±1.16 (4)
d DA 50 μM + fluphenazine 1 μM	0.06±0.08 (4)
e DA 50 μM + haloperidol 1 μM	0.42±0.18 (4)
f ADTN 50 μM	1.52±0.42 (4)

Values are means ± s.e.m. calculated as the total evoked release of ^{3}H-GABA in the 8-min period during and after application of a 4-min stimulus. The evoked release was calculated by subtraction of the average value for spontaneous ^{3}H-GABA efflux during the 6-min immediately before application of the stimulus (0.7–0.9% per min).

Müller cell localisation of glutamine synthetase in rat retina

IN retina as in brain, the metabolism of glutamic acid and γ-aminobutyric acid (GABA) is compartmentalised in biochemically defined pools[1–4]. When retinas are incubated *in vitro* with radioactive glutamate and GABA, the specific activity of the glutamine produced is greater than the specific activity of the total tissue glutamate. This indicates that glutamine is formed from a small glutamate pool of higher specific activity than the total glutamate pool. To understand better the metabolic organisation of these amino acids in retina, the anatomic localisation of the small glutamate pool is essential. There is evidence that Müller cells (retinal glia) may be the site of the small glutamate pool. Autoradiographic studies indicate that mammalian Müller cells take up GABA and glutamate[5–8]. Moreover, these cells contain succinic semialdehyde dehydrogenase[9] and GABA-transaminase[10] which are enzymes involved in the degradative metabolism of GABA. In a number of species, glutamine synthetase (GS), a key enzyme of the small glutamate pool[11], shows a striking increase in activity[12–14] which parallels the morphological development of the Müller cell[15–17]. We describe here the localisation of GS to Müller cells in rat retina by immunohistochemical techniques.

Normal adult albino rats were lightly anaesthetised with ether, and 1 ml of 1% sodium nitrite and 1,000 units of heparin sodium were injected intravenously. One minute later, rats were perfused for 15 min through the ascending aorta with 4% paraformaldehyde in 0.1 M sodium cacodylate buffer, *p*H 7.4, at room temperature. After perfusion, eyes were enucleated, bisected along the sagittal plane, and the vitreous body removed. Retinas were washed overnight at 4 °C in phosphate buffered saline (PBS) containing 10% sucrose. Retinas were then rinsed for 15 min in PBS containing 12% glycerol and 4% sucrose before quick freezing in a dry ice–95% ethyl alcohol mixture. Sections (10 μm thick) were obtained, treated with antibody to GS and processed with the indirect peroxidase-labelled antibody method[18,19]. Details of the preparation of the anti-GS antibody, its purification and characterisation have been described previously[20]. Briefly, immunoelectrophoretically proved monospecific antibody to sheep GS was prepared in rabbits and purified by affinity chromatography[21]. Rat and sheep GS were antigenically identical as determined by double immunodiffusion. Control sections were treated the same as experimental sections except that affinity-purified antibody to the soluble component of basement membrane (kindly provided by Dr Antonio Martinez-Hernandez) was substituted for the anti-GS antibody.

Sections of retina treated with anti-GS antibody and processed with the indirect peroxidase-labelled antibody

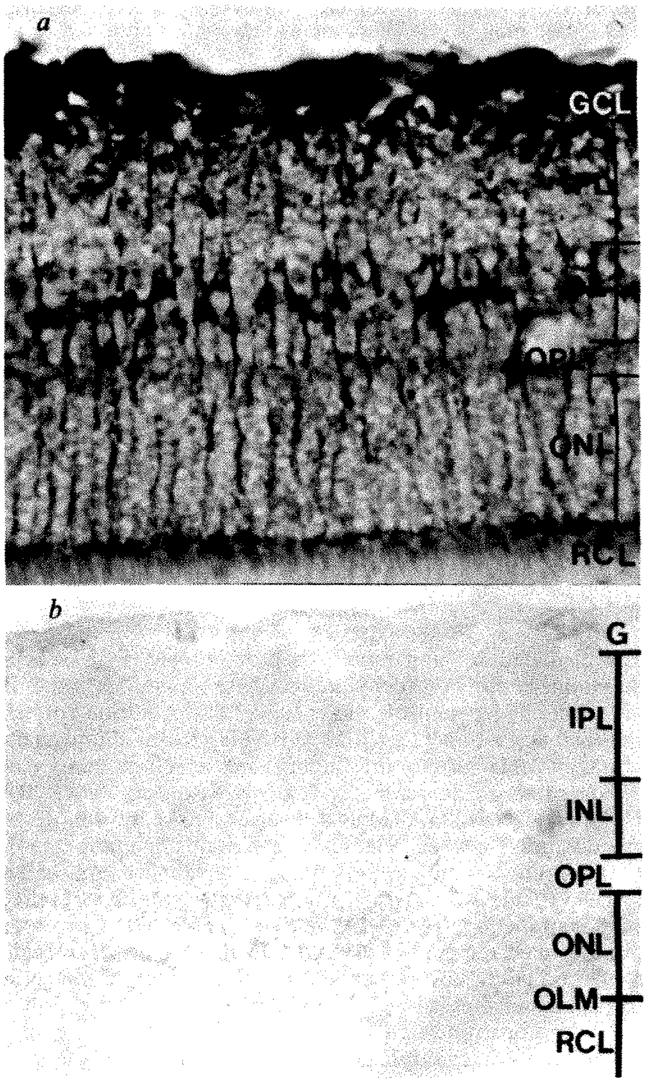

Fig. 1 *a*, Photomicrograph of rat retina cryostat section stained for glutamine synthetase by the indirect peroxidase-labelled antibody method. In the inner nuclear layer (INL), reaction product is conspicuous in Müller cell perikarya. Positive Müller cell processes extend in opposite directions from the inner nuclear layer. Densely stained areas are present in the ganglion cell layer (GCL) while small beads of reaction product form a thin line along the outer limiting membrane (OLM). RCL, rod and cone layer; ONL, outer nuclear layer; OPL, outer plexiform layer; IPL, inner plexiform layer. (× 300.) *b*, Control section: rat retina treated similarly to section in Fig. 1*a* except antibody to basement membrane was substituted for GS antibody. No reaction product is present. (× 300.)

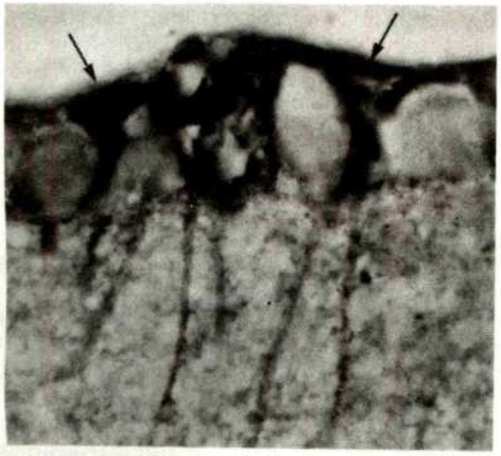

Fig. 2 Higher magnification of the ganglion cell layer demonstrates characteristic funnel-shaped Müller cell processes (arrows) containing deposits of reaction product. There is no staining in ganglion cells. (×750.)

method demonstrated that GS was confined to Müller cells (Fig. 1*a*). Peroxidase reaction product in the perikaryon clearly outlined the polygonal Müller cell nuclei located in the inner nuclear layer. Positive staining Müller cell processes were traced from the inner nuclear layer through the inner plexiform layer as narrow parallel columns ending in funnel-shaped deposits in the ganglion cell and nerve fibre layers (Fig. 2). Positive Müller cell processes also extended through the outer plexiform and outer nuclear layers to terminate as distinct beads of reaction product along the outer limiting membrane. The presence of GS in other glial elements could not be excluded. No reaction product was seen in photoreceptors, horizontal cells, bipolar cells, amacrine cells, or ganglion cells. Staining was not observed in retinas treated with control antibody (Fig. 1*b*).

This study has shown that retinal GS in the rat and therefore the small glutamate compartment associated with glutamine synthesis is localised to Müller cells, supporting the suggestion of Kennedy and co-workers[2]. Analogous to this finding is the localisation of GS to glia in rat brain[20]. Perhaps an integral role can now be assigned to the Müller cell in the GABA–glutamate–glutamine cycle proposed to occur in retina[1]. According to this concept, Müller cells take up neuronally-released glutamate and GABA, thereby inactivating and conserving these amino acids which are subsequently converted to glutamine by the action of GS. Glutamine, which is freely diffusible, then leaves the Müller cell and is available to neurones for the formation of glutamate and GABA. The localisation of GS to Müller cells thus lends firm support for a crucial role of these cells in GABA and glutamate metabolism.

We thank Dr Antonio Martinez-Hernandez for advice, Dr Paul Nakane for useful discussion and Mrs Katherine P. Bell for technical assistance. This study was supported by the Medical Research Service of the Veterans Administration and grant CA-15823 from the US NCI.

Electrical stimulation of denervated muscles reduces incorporation of methionine into the ACh receptor

ONCE a neuromuscular synapse has formed, the density of acetylcholine (ACh) receptors in the subsynaptic muscle membrane remains relatively constant, even after denervation of the muscle[1]. In contrast, the density of ACh receptors in the extrajunctional muscle membrane can vary widely. Extrajunctional receptors are present at high density in developing muscle, but are reduced to low levels during maturation of muscle fibres[2]. Their number is increased after denervation in the adult[3,4], and is again decreased on subsequent re-innervation of the muscle[5]. Several experiments have demonstrated that the amount and pattern of muscle activity strongly influence the density of extrajunctional ACh receptors (for review, see ref. 6), although other factors may be important as well[6–9]. Because extrajunctional receptors undergo continual turnover in the membrane[10–12], the effect of changes in activity on their density could result from alteration in rates of receptor synthesis or degradation. Recent experiments have shown that the reduction of receptor levels caused by stimulation in organ culture is accompanied by a decrease in the rate of receptor degradation[13]. These results imply that activity decreases the rate of receptor synthesis or its insertion into the membrane. In direct support of this idea, we report that electrical stimulation of denervated muscle reduces incorporation of ^{35}S-methionine into ACh receptors.

Left hemidiaphragms from male Sprague–Dawley rats (50–60 g) anaesthetised with ether were denervated by intrathoracic transection of the phrenic nerve. Three or four days later, denervated hemidiaphragms with ribs attached were removed from the animals, pinned out in pairs in Sylgard lined culture dishes, and incubated in 12 ml Trowells T8 medium as described previously[10,13]. One hemidiaphragm of each pair received direct electrical stimulation by platinum electrodes recessed in the Sylgard beneath the muscle[13], whereas the other muscle was not stimulated. Suprathreshold square pulses of 2 ms duration and alternating polarity were applied to the muscles at 40 Hz for 350 ms once every 3 s. After 17–53 h in culture, the medium was changed and the muscles incubated for 1 h with Trowells medium modified to contain a low concentration of methionine (2×10^{-6} M). ^{35}S-methionine (0.5.0 mCi; 300–500 mCi mmol^{-1}; New England Nuclear) in modified T8 medium was then added to each dish and the muscles labelled for 6–12 h.

The incorporation of ^{35}S-methionine into the ACh receptor was determined after purification by affinity chromatography on cobrotoxin–Sepharose and concanavalin A (con A–Sepharose) as depicted in Fig. 1. Diaphragms were removed, blotted dry, weighed and homogenised. A

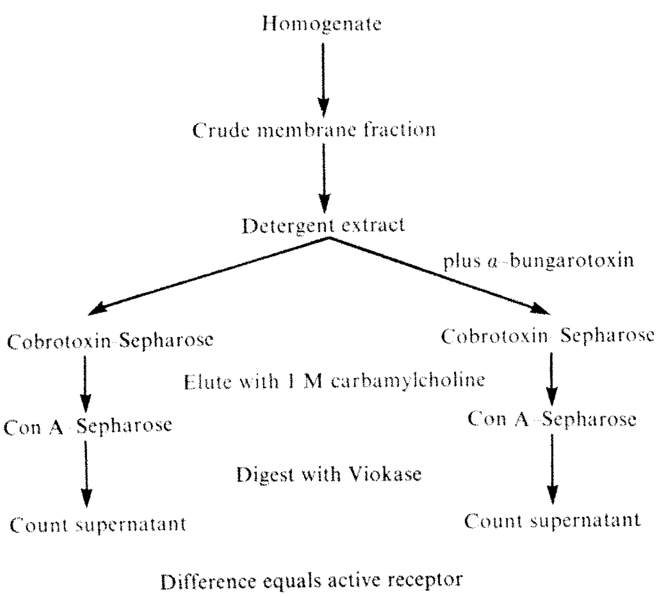

Fig. 1 Schematic outline of the procedure used to measure ^{35}S-ACh receptor. Details are provided in the text and in Table 1.

crude membrane fraction was extracted with Triton X-100 (ref. 14), and the extract was divided into two equal portions. Excess unlabelled α-bungarotoxin was added to one portion (final concentration 10^{-5} M), and both were incubated at room temperature for 15 min. The extracts were applied to parallel columns of cobrotoxin–Sepharose and eluted with carbamylcholine[14]. Incubation with unlabelled toxin before the column step specifically prevents adsorption of the receptor (Froehner & Hall, unpublished) and the eluate of the column receiving this extract contained only contaminating radioactivity, thus serving as a control for the paired eluate. Because the amount of contaminating radioactivity at this stage was large and variable, further purification was necessary. Since ACh receptor is a glycoprotein which binds to con A (ref. 15) additional purification was achieved by adsorbing each of the paired eluates with con A–Sepharose. Material retained on this column was digested with Viokase and the released radioactivity measured by liquid scintillation spectrometry.

Results from a typical experiment are shown in Table 1. The amount of radioactive receptor was calculated as the difference between each sample and its paired control. Ratios of radioactive receptor, corrected for wet weight, were then computed for each pair of stimulated and unstimulated muscles. Control experiments established that receptor from both stimulated and unstimulated muscles was recovered equally well from the cobrotoxin–Sepharose and was quantitatively retained on con A–Sepharose.

Results of ten experiments in which muscles were stimulated for 1–3 d are shown in Table 2. Stimulation of the muscles reduced the total amount of ACh receptor present in muscle extracts and reduced incorporation of ^{35}S-methionine into the receptor. Both the reduction in total amount of receptor and in the extent of incorporation were greater with longer periods of stimulation. Complete inhibition of synthesis was not observed even after 3 d. The residual synthesis probably reflects inadequate stimulation of some fibres[13], but could be due to suboptimal parameters of stimulation or to the presence or absence of some factor unrelated to activity.

Because the phasic pattern of stimulation used in these experiments was different from the stimulation (2–10 Hz) used in earlier experiments[13], we repeated our previous comparison of receptor degradation in stimulated and unstimulated muscles. When muscles were stimulated phasically, the rate of receptor degradation ($t_{1/2} = 12.08 \pm 0.8$ h, $n = 3$) was not significantly different from that found without stimulation ($t_{1/2} = 11.8 \pm 0.9$ h, $n = 3$). These results are in agreement with our previous conclusions that the decrease in ACh receptor levels in stimulated muscle is not caused by an increased rate of breakdown.

Incorporation of ^{35}S-methionine into richloroacetic acid (TCA)-precipitable material in the Triton X-100 extracts from stimulated muscles was identical to that found in control muscles (105±9%, mean±s.e.m., $n = 10$). Thus it is unlikely that differences in specific activity of intracellular methionine could account for the difference we have observed. Autoradiographs of two-dimensional gels[16] of the labelled extracts from stimulated and unstimulated muscles were almost identical, differing only by a few proteins. Since neither the major patterns of protein synthesis nor the total amount of isotope incorporated is changed by stimulation, the effect on ^{35}S-methionine incorporation into receptor must be relatively specific.

The amount and pattern of muscle activity is known to affect several other properties of muscle fibres besides extrajunctional ACh receptor level. These include the species of myosin light chains made by the fibres[17], the rate of synthesis of myosin heavy chain[18], the amount of acetylcholinesterase activity in the muscle[19] and several physiological properties of the muscle, the biochemical basis of which is not known[6]. Many of these changes seem to be controlled at the level of gene expression[20,21]. The mechanism by which muscle activity mediates these effects is a major question for future investigation.

Previous experiments have shown that incorporation of

Table 1 Determination of ^{35}S-receptor

α-BUTX, α-Bungarotoxin.

Two left hemidiaphragms that had been denervated 4 d earlier were cultured for 3 d and labelled with 1 mCi ^{35}S-methionine for the final 12 h. The stimulated and unstimulated muscles weighed 66 and 78 mg, respectively. Each was homogenised in 1 ml 50 mM Tris-HCl, *p*H 7.4, 50 mM NaCl with 1 mM EDTA, 1 mM EGTA, 0.4 mM phenylmethylsulphonyl fluoride (PMSF), 20 U ml^{-1} Trasylol (Sigma) and 0.1 μg ml^{-1} Pepstatin. Homogenates were diluted to 5 ml with buffer and centrifuged at 48,000 r.p.m. for 45 min in a Spinco SW 50.1 rotor. The pellet was resuspended in 500 μl of the above buffer, Triton X-100 was added to a final concentration of 3% and extraction carried out on ice for 1 h. The extract was centrifuged at 20,000*g* for 1 h and the resultant supernatants were each divided into two equal portions. To one aliquot of extract from each muscle was added α-bungarotoxin (final concentration 10^{-5} M α-BUTX); followed by incubation of each portion for 15 min at room temperature. Four 0.3-ml cobrotoxin–Sepharose[14] (400 μg cobrotoxin per ml bed volume) columns were poured and washed consecutively with 50 mM Tris-HCl, *p*H 7.4, 1% Triton X-100 (TT) containing 1 M NaCl and with 50 mM Tris-HCl, *p*H 7.4, 50 mM NaCl and 1% Triton X-100 (TNT). The pre-incubated extracts were then adsorbed on to the columns at 4 °C, and the columns washed sequentially with TNT (5 ml), TT+1 M NaCl (10 ml) and TNT (5 ml). In each case no radioactivity was detectable in the final wash. ACh receptor was then eluted with several column volumes of TNT which contained 1 M carbamylcholine chloride, *p*H 8.6, and 0.4 mM PMSF, 20 U ml^{-1} Trasylol and 0.1 μg ml^{-1} Pepstatin. Duplicate 25-μl aliquots from 1-ml eluates were counted and the remainder adsorbed to pre-washed 0.5 ml con A–Sepharose columns (2 mg con A ml^{-1} bed volume). After the columns were washed with TNT to remove non-adsorbed radioactivity, the resin was mixed with 0.5 ml 3 mg ml^{-1} Viokase in TNT and incubated overnight at 37 °C. The con A–Sepharose was removed from suspension by centrifugation and the supernatant radioactivity determined.

Table 2 Effect of stimulation on ACh receptor synthesis

Duration of culture (h)	Duration of labelling (h)	Total ACh receptor stimulated/ unstimulated	^{35}S-ACh receptor stimulated/ unstimulated	n
24*	6	$81 \pm 4\%$	$42 \pm 7\%$	4
51†	6	$39 \pm 10\%$‡	$23 \pm 7\%$	3
66†	12	$28 \pm 8\%$‡	$14 \pm 2\%$§	3

*Denervated 3 d before culture.
†Denervated 4 d before culture.
‡Significantly different from 24 h stimulation $P < 0.005$.
§Significantly different from 24 h stimulation $P < 0.05$.

Effect of stimulation on ACh receptor synthesis. Culture duration is indicated. ^{35}S-methionine was present in the culture for the time shown just before termination of the experiment. Total ACh receptor was determined by a DEAE filter-binding assay of ^{125}I-α-bungarotoxin as described previously[14]. ^{35}S-ACh receptor determined as indicated in Table 1. Values expressed as the mean ±s.e.m. n equals the number of muscle pairs. In two cases (24 h and 66 h of culture, respectively) no difference (100%; 102%) in incorporation was observed between stimulated and control muscles. Total ACh receptor was reduced in both cases; therefore, either stimulation was effective only during part of the culture period before labelling, or recovery of radioactivity was not the same for control and stimulated muscles. Because of the large, statistically significant variation of these values from the others, results from these two experiments have been excluded from the data in Table 2. Their inclusion, however, would not affect the general conclusions to be drawn.

^{35}S-methionine into the ACh receptor can be detected in denervated muscles only after accumulation of extrajunctional receptor begins[22]. These results along with those reported here show that changes in incorporation of ^{35}S-methionine into ACh receptor parallel changes in overall receptor density and suggest that extrajunctional receptor levels are controlled by regulation either of synthesis or of some other step before appearance of the receptor in the external membrane.

High conductance in an epithelial membrane not due to extracellular shunting

THERE is conclusive evidence for a cellular and extracellular route for ions across epithelial tissues[1]. The extracellular pathway is constituted by the tight junctions and the lateral intercellular space. Epithelia have been classified as 'tight' or 'leaky' depending on the ratio of the conductances of both pathways (that is, in a tight epithelium the ratio: $g_{\mathrm{shunt}}/g_{\mathrm{cell}} \leqslant 1$) Moreover, tight epithelia have transmural resistances and electrical potentials far greater than those observed in leaky epithelia. We report here that the epithelium of rabbit salivary duct does not confine to this rule since it combines several characteristics of tight epithelia with resistance values as low as in proximal tubules of the kidney, an extremely leaky epithelium. Permeability studies with polar non-electrolytes support the conclusion that the high conductance is not due to extracellular shunting. Our study implies that the magnitude of the epithelial resistance does not determine whether an epithelium is tight or leaky.

Main ducts of rabbit salivary glands were dissected and mounted in a perfusion chamber as before[2]. Transductal resistance was measured by a direct method. We developed a combined current passing and potential sensing electrode small enough to fit into the lumen of the duct. Details of the electrode are published elsewhere[3]. Ductal permeability to non-electrolytes was determined by conventional isotope techniques. Unidirectional fluxes of labelled compounds were measured from serosa to mucosa. Ringer solutions contained (in mM): Na, 145; K, 4; Mg, 1; HCO_3, 25; acetate, 10; pyruvate, 10; pH, 7.4. The other anions were Cl, 100 or SO_4, 50 respectively. Sulphate solutions have mannitol to restore isotonicity and also 2 mM Cl for proper functioning of the Ag/AgCl electrode[3]. The serosal solution contained in addition 6 mM glucose and protein (Haemacel, 30 g l^{-1}) to keep ductal transport optimal[2].

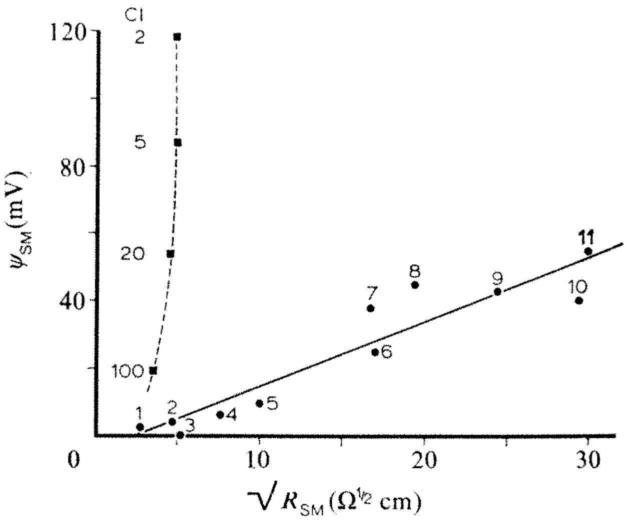

Fig. 1 Relationship between transepithelial potential (ψ_{SM}) and the square root of resistance in various epithelia (straight line). (1), Proximal tubule, rabbit (ref. 4); (2), ileum, rabbit (ref. 5); (3), gall bladder, rabbit (ref. 6); (4), gall bladder, human (ref. 7); (5), early distal tubule, rat (ref. 8); (6), colon, rabbit (ref. 9); (7), gastric mucosa, lizard (ref. 10); (8), late distal tubule, rat (ref. 11); (9), late distal tubule, dog (ref. 12); (10), collecting duct, rabbit (ref. 13); (11), collecting duct, hamster (ref. 14). The dashed line gives values of ψ_{SM} and $\sqrt{R_{SM}}$ measured for rabbit main duct in solutions with varying Cl-concentrations. Solutions were symmetrical and the number indicate Cl concentration. In low-Cl solutions current pulses induced strong polarisation effects and voltage responses were extrapolated to $\mathrm{d}V/\mathrm{d}I$ ($t \to 0$). In high-Cl solutions polarisation effects were minimal. Our resistance values in high Cl solutions agree well with values obtained from applying cable theory as reported by Fromter *et al.*[24]. $y = 1.89x - 4.2$; $r = 0.94$.

In Fig. 1 electrical potentials (Ψ_{SM}) are plotted against the square root of resistance values ($\sqrt{R_{SM}}$) reported for various epithelial tissues. The correlation between these parameters is highly significant, indicating that the smaller the extracellular shunt conductance the higher the values for Ψ_{SM} and R_{SM}. The dashed line in Fig. 1 gives that same relation for salivary duct epithelium, which shows a totally different behaviour. Besides the fact that Cl ions have a strong short circuiting effect on the potential we observed in SO_4 solutions potentials up to 140 mV combined with resistance values as low as 10 Ω cm^2. Potentials of the same magnitude have been reported only for tight epithelia with resistance values three orders of magnitude greater[16]. Cl ions have also a short-circuiting effect on frog skin potentials, although less pronounced[15].

In Fig. 2 values of Ψ_{SM} and $\sqrt{R_{SM}}$ are plotted as a variation among 23 main ducts, measured immediately after mounting in SO_4 solutions. There is a statistically significant inverse relationship between these two parameters. A similar inverse relationship has been reported for urinary bladders, however, only when special measures were taken to exclude edge damage effects[16,17]. Evidently an inverse relationship will not occur when a 'passive' extracellular shunt determines the variation in the transepithelial resistance. The phenomenon can be explained when the rate of active Na-transport is regulated by the Na-conductance of the luminal cell membrane[16]. A greater Na conductance would then evoke higher rates of Na pumping in the contraluminal membrane. Figures 1 and 2 show clearly that the main duct combines tight epithelial properties with resistance values normally observed in very leaky epithelia. The results given in Table 1 support this ambiguity. Permeabilities to polar non-electrolytes in the main duct are of the same order as those in the toad urinary bladder. The apparent impermeability to inulin suggests that a significant paracellular shunt for non-electrolytes is absent. On the other hand, a greater P_{Cl} value reflects the low resistance of the duct.

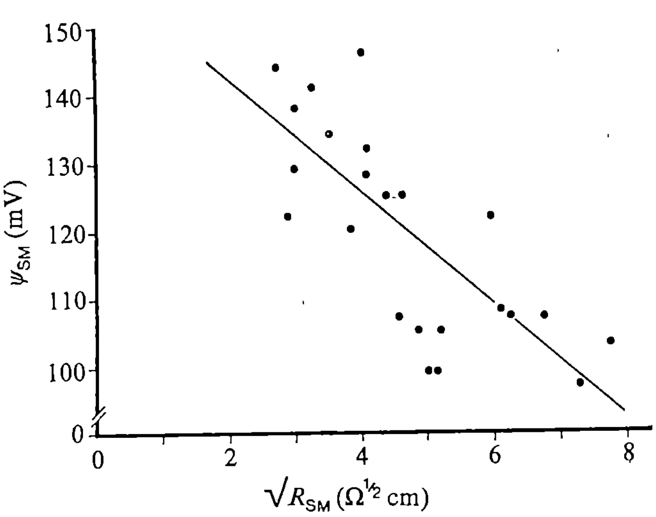

Fig. 2 Inverse relationship between potential difference (ψ_{SM}) and resistance ($\sqrt{R_{SM}}$) as a variation among 23 main ducts measured in symmetrical SO_4 solutions with 2 mM Cl. $y = -8.25x + 158.3$; $r = 0.75$.

Three more arguments are in favour of ranking ductal epithelium as tight despite the low resistance. The natriuretic drug amiloride inhibited net Na-transport in salivary duct completely when it was applied to the mucosal solution (10^{-4} M). In SO_4-solutions ductal resistance increased from 22.3±1.8 to 91.4±12.6 Ω cm^2 ($n = 7$) after addition of amiloride. In Cl-solutions the increase was less pronounced (from 6.6±0.4 to 14.1±0.7 Ω cm^2, $n = 4$). The relative increase in resistance is comparable with amiloride treatment of frog skin[16].

Table 1 Permeability of main duct, urinary bladder and gallbladder to polar non-electrolytes

	Rabbit submaxillary main duct	Toad urinary bladder	Rabbit gall bladder (ref. 19)
Solute	(10^{-7} cm s^{-1})	. (10^{-7} cm s^{-1})	(10^{-7} cm s^{-1})
Urea	56	14 (ref. 18)	890
Sucrose	6.5	5.1 (ref. 17)	76
Inulin	n d.	n.d. (ref. 17)	29
Cl^-	550 (ref. 21)	13 (ref. 17)	—

The tubular perfusion rate was 12.5 µl min^{-1}. P values of main duct are quoted as the mean estimated from five estimates (n.d., not detectable). P_{Cl} was determined in ducts with open circuit. P_{Cl} was independent of the electrical potential (for detailed discussion see ref. 21).

In Cl-solutions we measured a net Na-absorption rate of 587 nEq min^{-1} cm^{-2}, comparable with 683 nEq. min^{-1} cm^{-2} reported by Martin *et al.*[22], corresponding with 0.94–1.10 mA cm^{-2}. Potential and resistance values in this condition were 12.3±2.4 mV and 10.8±1.9 Ω cm^2 ($n = 9$). From these values a short-circuit current (SCC) of 1.14 mA cm^{-2} can be calculated which equals net Na-transport. The SCC is only equal to net Na-transport in tight epithelia[17,23]. Furthermore, salivary duct epithelium responds asymmetrical to cation gradients contrasting with symmetrical responses in leaky epithelia[24].

Interestingly, the resistance of cell membranes can be as low as 10 Ω cm^2—we found no reason to ascribe this low resistance to an extracellular shunt pathway.

From the unusual combination of low resistance and electrical properties of tight epithelia we have to conclude that the only criterion whether an epithelium is 'tight' or 'leaky' is the conductance ratio of the cellular and extracellular route since the electrical resistance alone is not sufficient to discriminate between the two classes of epithelia.

Fluorescent probe detects redistribution of cell calcium during stimulus–secretion coupling

STIMULUS-secretion coupling in pancreatic acinar cells is believed to be mediated by a rise in intracellular Ca^{2+} activity[1–5]. Based on the observation that physiological secretagogues trigger a rapid increase of Ca^{2+} efflux[3,4] and stimulate enzyme release even in the absence of extracellular calcium[2,4,5], it has been proposed that stimulus–secretion coupling involves a redistribution of intracellular calcium[3,5,6]. Since most calcium in pancreatic acinar cells is bound to membranes or is sequestered in mitochondria[7], we have attempted to monitor these calcium stores during secretion by using the fluorescent probe chlorotetracycline (CTC). This probe forms highly fluorescent complexes with Ca^{2+} and Mg^{2+} in the presence of biological membranes or detergent miceles[8,9] and has been successfully used in isolated mitochondria[10,11] and sarcoplasmic reticulum vesicles[12] to monitor calcium movements induced by substrates and inhibitors. In this report, we show that fluorescence of CTC associated with pancreatic acinar cell membranes decreases rapidly on stimulation of enzyme secretion and that this intensity change is preferential for CTC complexed to calcium.

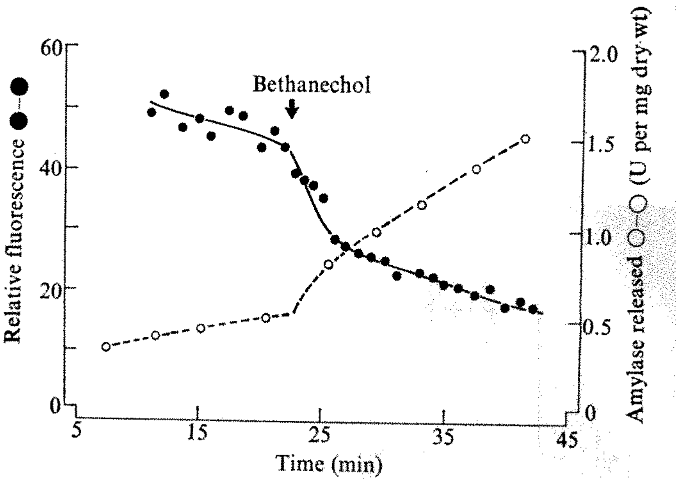

Fig. 2 CTC fluorescence of and amylase release from dissociated pancreatic acini. Acini were loaded with CTC as described in Fig. 1, then stirred periodically in a fluorometer cuvette maintained at 37 °C. Fluorescence was monitored as in Fig. 1. Amylase released into the medium was measured by removing 0.2 ml aliquots of the suspension at the designated times, centrifuging at 8000*g* for 20 s, and assaying amylase in the supernatant by the method of Rinderknecht *et al.*[16]. Amylase activity is expressed in international units per mg dry wt of acini; the cuvette contained 1.47 mg dry wt of acini ml^{-1}. Addition of bethanechol at the arrow (final concn = 1.25×10^{-4} M) elicited a rapid decrease in fluorescence and a 240% increase in the rate of amylase release. These results are representative of six similar experiments.

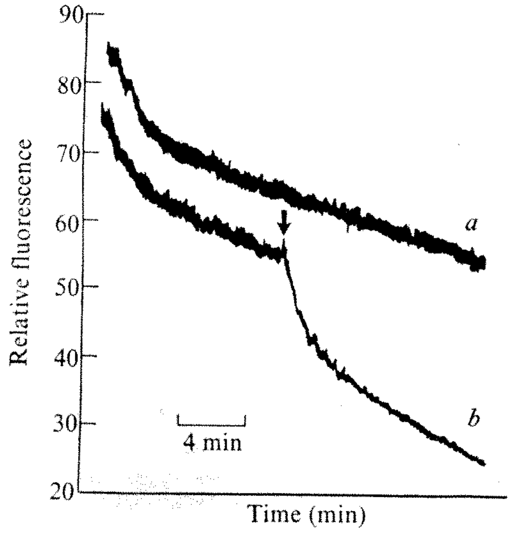

Fig. 1*a*, Effect of bethanechol on the fluorescence of dissociated acini loaded with chlorotetracycline (CTC). Enzymatically dissociated acini were prepared from the pancreata of 8 to 12 fasted male Swiss white mice by the method of Amsterdam and Jamieson[14] modified to exclude the Ca^{2+} chelation step[15]. Acini were preincubated for 60 min in a Tris-buffered Ringer (TR)[2] containing 1% bovine serum albumin (BSA) and 10^{-4} M CTC. Acini were then washed and resuspended in 4 ml of TR containing no BSA or CTC and the suspension placed in a cuvette in an Aminco-Bowman spectrofluorometer having a band pass of 15 nm and modified so as to allow continual stirring and temperature control at 37 °C. Excitation of CTC fluorescence was at 400 nm and emission monitored at 525 nm. *b*, Bethanechol (final concn = 10^{-4} M) was added at the arrow and resulted in a rapid loss of fluorescence intensity. This experiment was representative of 22 similar experiments.

Enzymatically-dissociated pancreatic acini were pre-incubated 60 min in 10^{-4} M CTC, then resuspended in buffer containing no CTC and placed in a fluorometer cuvette. The fluorescence intensity of these acini decreased with time, the decrease usually being faster in the first 5 min of resuspension and slower thereafter (Fig. 1*a*). Application of the cholinergic agonist, bethanechol, during the slower phase (Fig. 1*b*) elicited a marked loss of fluorescence occurring largely in the first 6 min of secretagogue action. After this time, fluorescence intensity continued to decrease at a rate similar to that before bethanechol addition. The secretagogue-induced fluorescence decrease and a stimulation of amylase release into the medium could be measured simultaneously on acini incubated in a cuvette as shown in Fig. 2. As observed previously, an increased loss of fluorescence occurred in the 5 min following bethanechol addition. At the same time, the rate of amylase release measured 5–15 min after the addition of bethanechol was increased by 240% over the control rate measured in the 15 min before adding bethanechol. This suggests that the CTC present in these acini did not interfere with normal stimulation of secretion, a result supported by experiments in which acini pre-incubated 60 min with and without 10^{-4} M CTC released identical amounts of amylase in response to bethanechol (not shown).

Two observations indicated that the fluorescence signal from CTC-loaded acini was emitted largely from probe molecules incorporated into intracellular membranes which bind Ca^{2+} and Mg^{2+}. First, fluorescence microscopy showed that CTC fluorescence in acinar cells had a distribution similar to that of intracellular membranes[13]. Second, the fluorescence excitation spectrum of CTC in acinar cells was like that of CTC complexed with divalent cations in an amphipathic environment (λ_{max} = 386–400 nm) but unlike that of free CTC (λ_{max} = 382 nm) or of CTC complexed with divalent cations in aqueous solutions. In this environment, CTC fluorescence could be decreased by dissociation of its divalent cation complexes or by subsequent partitioning of the probe out of the membrane. We have detected, in fact, an increased exit of CTC from pancreatic acini during stimulation as well as the rapid decrease in fluorescence. This exit was not due to loss of CTC associated with contents of secretory granules since doses of bethanechol that elicited maximal amylase release produced fluorescence changes that were only 30% of maximum. Furthermore, fluorescence microscopy showed that secretory granule contents do not fluoresce[13]. Rather, studies with isolated mitochondria have indicated that complex dissociation and probe

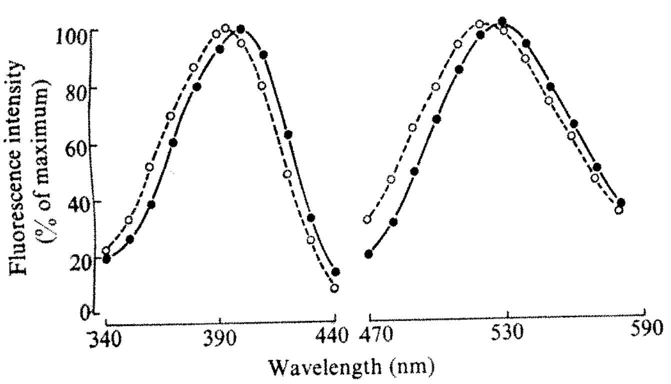

Fig. 3 Excitation and emission spectra of acinar cell-associated CTC immediately before (●) and 9 min after (○) bethanechol stimulation. Pancreatic acini were loaded with CTC, and their fluorescence monitored as described in Fig. 1. Spectra were corrected by subtracting the light scattering of an acini suspension not treated with CTC, then normalised to more clearly demonstrate the spectral shifts. Fluorescence intensity of maxima before and after stimulation were 70 and 45 units respectively. These spectral shifts were observed in each of five experiments with bethanechol and in four experiments using caerulein.

exit both occur when divalent cations dissociate from membranes containing CTC[10]. Thus, a reasonable explanation for the bethanechol-induced decrease in fluorescence is that Ca^{2+} or Mg^{2+} is released from some intracellular membrane.

Since Ca^{2+} and Mg^{2+} complexes of CTC can be distinguished by their excitation and emission spectra, we decided to record these spectra from CTC-loaded acini before and after stimulation. Normalised spectra in Fig. 3 show that before stimulation excitation and emission maxima were at 399 nm and 526 nm respectively. After stimulation these maxima were shifted to 393 nm and 520 nm. For comparison, model studies were done using 10^{-5} M CTC in 90% methanol-10% 10 mM Tris-HCl, *p*H 7.4, an amphipathic solvent in which the Ca^{2+} and Mg^{2+} complexes of CTC exhibit spectra similar to those in membrane environments[10]. In this slovent, Ca^{2+}–CTC exhibited excitation and emission maxima at 398 nm and 529 nm respectively, while these maxima for Mg^{2+}–CTC were at 386 nm and 519 nm. Thus, spectra from CTC-loaded acini indicated that CTC was complexed largely with Ca^{2+} before stimulation and largely with Mg^{2+} after stimulation. We concluded that the bethanechol-induced fluorescence decrease involved a preferential loss of signal from CTC complexed with Ca^{2+} in a membrane environment.

An intensity decrease accompanied by similar spectral shifts was also observed during stimulation by caerulein, a polypeptide containing the active site of CCK-PZ. The decrease in CTC fluorescence induced by bethanechol was blocked by atropine whereas that induced by caerulein was not. The fluorescence decrease in response to either secretagogue could be observed in the absence of extracellular calcium which was also the case for amylase release[2].

In control experiments, acini exhibited no changes in fluorescence intensity on stimulation when loaded with 1-anilino-8-naphthalenesulphonate (ANS) or oxytetracycline,-fluorescence probes that are not sensitive to membrane-bound divalent cations.

In view of the known sensitivity of chlorotetracycline fluorescence to membrane-bound divalent cations[8-12], these data are direct evidence for a release of calcium from intracellular membranes during stimulus–secretion coupling in pancreatic acinar cells. We are currently using chlorotetracycline to study the site and mechanism of this calcium release.

This study was supported by grants from the National Cystic Fibrosis Research Foundation and the NIGMS of the USPHS.

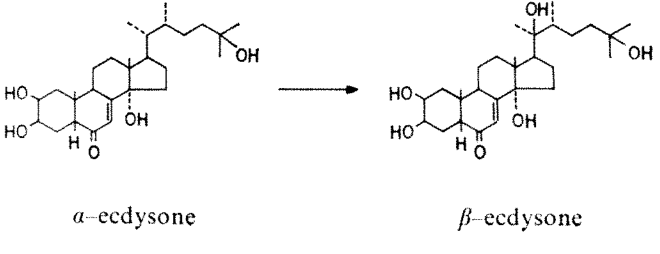
Evidence for an α-ecdysone cytochrome P-450 mixed function oxidase in insect fat body mitochondria

IT is now evident that α-ecdysone, a polyhydroxylated steroid, is synthesised and secreted by the insect prothoracic (ecdysial) glands[1-3]. β-ecdysone (20-hydroxy-α-ecdysone) seems, however, to have the major role in eliciting moulting during the post-embryonic development of insects[4]. If α-ecdysone functions as a pro(pre)-hormone as has been suggested[1,4], then it must undergo hydroxylation at C-20 of the side chain to form the moulting hormone, β-ecdysone. This conversion of α- to β-ecdysone is carried out by a hydroxylase which is located in tissues peripheral to the prothoracic glands[1,5,6]. Little is known about the subcellular distribution of this enzyme complex and there is virtually no information regarding the type of enzyme complex responsible for the oxygenation of steroids in insects in general. Using the vertebrate mixed function oxidase system as a model, we have investigated the subcellular distribution and enzymatic characteristics of the insect C-20 hydroxylase in last instar larvae of the tobacco hornworm, *Manduca sexta.*

In vertebrates, steroid hormone hydroxylations are catalysed by hydroxylase systems possessing a terminal cytochrome P-450 (refs 7 and 8). These enzyme complexes, termed mixed function oxidases or mono-oxygenases, incorporate one atom of molecular oxygen into substrate while reducing the other

Fig. 1 Stoichiometry of a cytochrome P-450 mixed function oxidase type reaction and the C-20 hydroxylation of α- to β-ecdysone.

$$\mathrm{RH + NADPH + H^{+} + O_2 \longrightarrow ROH + NADP^{+} + H_2O}$$



atom to water (Fig. 1). These P-450 mixed function oxidases are located in mitochondria and/or microsomes, are NADPH dependent and exhibit a characteristic CO difference spectrum absorption maximum at A_{450}. Since the C-20 hydroxylation of α-ecdysone in insects has characteristics in common with the P-450 mixed function oxidases mediating the hydroxylation of vertebrate steroid hormones (Fig. 1), it is reasonable to suggest that oxygenation of α-ecdysone is carried out by a similar enzyme complex.

C-20 hydroxylase activity was examined in whole tissues and homogenates incubated *in vitro* with 23,24-^{3}H-α-ecdysone (58 Ci mM^{-1}) to determine relative tissue hydroxylase activity. For both whole tissues and homogenates, the highest hydroxylase activity was associated with fat body, with lesser activity exhibited by Malpighian tubules, body wall, midgut, and perhaps salivary glands. C-20 hydroxylation of α-ecdysone did not occur in prothoracic glands, nerve cord, muscle, wing disks and haemolymph. Due to the high hydroxylase activity of the fat body, its abundance relative to other tissues, its accessibility and role as the major metabolic organ in insects, it was the tissue of choice for fractionation studies and biochemical characterisation of the C-20 hydroxylase.

Subcellular fractions of fat body homogenates were obtained by differential centrifugation and the C-20 hydroxylase activity determined (Table 1). The majority of the enzyme activity was associated with the mitochondrial fraction (64%), with reduced levels in the nuclear and microsomal fractions and none in the postmicrosomal supernatant. When the subcellular fractions were reconstituted, the C-20 hydroxylase activity for those pooled fractions approximated the sum of the activity for the individual fractions. This suggested that the enzyme activity associated with the nuclear and post-mitochondrial fractions may be a consequence of mitochondrial contamination. To verify this, the structural components of the subcellular fractions were examined by electron microscopy. The principal organelle observed in each fraction corresponded to what was expected, and the relative distribution of mitochondria correlated with the distribution of C-20 hydroxylase activity in the respective fractions. Mitochondrial and post-mitochondrial marker enzyme activities, cytochrome oxidase[9] and glucose-6-phosphatase[10] (possibly trehalose-6-phosphatase in insects[11]), respectively, were then monitored in each fraction and their distribution compared with that for the C-20 hydroxylase (Table 1). The percentage distribution of activity for the mitochondrial marker enzyme was consistent with that observed for the C-20 hydroxylase, whereas the post-mitochondrial enzyme activity was associated with the lowest C-20 hydroxylase activity. Therefore, on the basis of these data, it seems that the α-ecdysone C-20 hydroxylase is a mitochondrial enzyme and that the activity of the nuclear and microsomal fractions is due to mitochondrial contamination. This agrees with recent preliminary reports in which mitochondrial fractions from the midgut of *M. sexta*[12] and Malpighian tubules of the locust

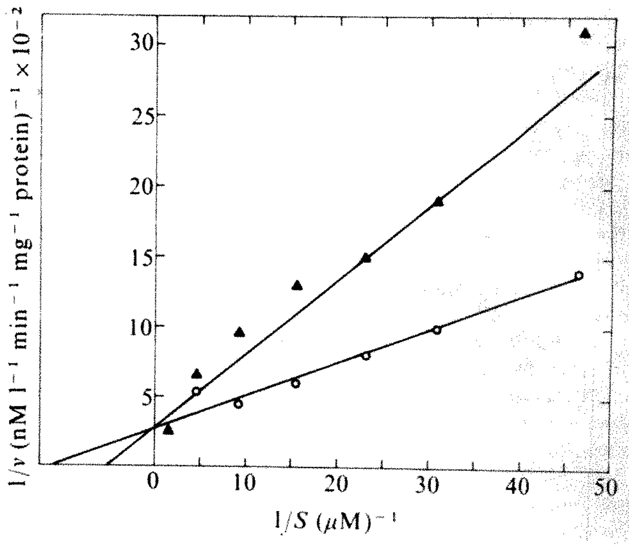


Fig. 2 Lineweaver–Burk plot for metyrapone inhibition of the fat body mitochondrial C-20 hydroxylase. The K_i for metyrapone (▲) is 3.9×10^{-6} M with a correlation coefficient of 0.997. The K_m for α-ecdysone is $1.6 \pm 0.7 \times 10^{-7}$ M (mean ± s.d. of 8 determinations). The K_m for α-ecdysone (○) in determining the metyrapone K_i was 9.0×10^{-8} M.

Table 1 Distribution of α-ecdysone C-20 hydroxylase, cytochrome oxidase and glucose-6-phosphatase activities in subcellular fractions of *M. sexta* larval fat body

Fraction	β-Ecdysone generated		Relative activity	
	ng	Relative activity	Cytochrome oxidase	Glucose-6-phosphatase

M plus PMS	0.22	0.69		
N plus M plus PMS	0.31	0.97		

Fat body from day 1 fifth instar *M. sexta* larvae was homogenised (50 mg ml^{-1}) in 0.05 M $NaH_2PO_4 \cdot Na_2HPO_4$ buffer (*p*H 7.5) containing 0.25 M sucrose at 0 °C. Subcellular fractions were obtained by differential centrifugation at –5 °C: nuclear, 800*g* for 10 min; mitochondrial, 12,000*g* for 10 min; microsomal, 105,000*g* for 1 h. Pellets were washed once and resuspended in the same buffer to the original concentration of 50 mg tissue equivalents ml^{-1}. For the C-20 hydroxylase assay, 0.05 ml subcellular fraction was incubated with 0.05 ml (0.05 M $NaH_2PO_4 \cdot Na_2HPO_4$ buffer (*p*H 7.5) containing 1.5×10^5 d.p.m. 23,24-^{3}H-α-ecdysone (58 Ci mM^{-1}, 1.2×10^{-8} M) and 37.5 μg NADPH (4.0×10^{-4} M) for 30 min at 30 °C. All assays were run in duplicate. Ethanol (2.0 ml) was added to terminate the reactions. Terminated assays were centrifuged (10,000*g* for 10 min) and 200 μl of the supernatant (1.5×10^4 d.p.m.) plus 1.0 μg carrier α- and β-ecdysone were streaked on thin layer plates (EM, silica gel 60, F-254) and developed in a solvent system of chloroform: 95% ethanol, 80: 20 (v/v). Following visualisation of the α- and β-ecdysone bands under ultraviolet light, these zones were scraped and counted. The efficiency of separation was greater than 94 ± 2.5% that obtained using high-pressure liquid chromatography[3]. Cytochrome oxidase[9] and glucose-6-phosphatase[10] activities, as well as protein concentrations[18], were determined as described previously. Glucose-6-phosphatase has not been demonstrated to be a microsomal marker enzyme in insects but has been shown to be associated with postmitochondrial fractions, and may actually be trehalose-6-phosphatase, which is a post-mitochondrial enzyme in insects[11]. Since trace amounts of substrate were used for the C-20 hydroxylase assay, potential compartmentalisation of endogenous α-ecdysone into selected subcellular fractions could have reduced the apparent hydroxylase activity in these fractions. Therefore, the endogenous α-ecdysone in each fraction was determined by radioimmunoassay and was observed to be the same for all fractions (concentrations ~ 2×10^{-2} of the ^{3}H-α-ecdysone used for the assay).

Schistocerca gregaria (H. Rees, personal communication) exhibited C-20 hydroxylase activity.

To characterise the C-20 hydroxylase as a mixed function oxidase, it was necessary to demonstrate that the hydroxylation was enzymatically mediated. Enzyme activity profiles under varying regimens of temperature and pH were obtained, with the observed optima being 30 °C and pH 7.5, respectively. The reaction was not affected by most monovalent and divalent cations, but Mg^{2+} ions inhibited hydroxylation (up to 25%) at concentrations as low as 10 mM. Time course analysis of substrate conversion revealed a linear response up to 60 min with a plateau obtained at 90 min. When increasing concentrations of mitochondria were incubated with fixed levels of substrate, proportionate increases in the hydroxylation of substrate to product were observed. Hyperbolic saturation kinetics were obtained when increasing levels of substrate were incubated with fixed concentrations of mitochondria. An apparent K_m of $1.6 \pm 0.7 \times 10^{-7}$ M (mean ± s.d.) was derived from Lineweaver–Burk plots obtained by linear regression analysis of saturation kinetics data (Fig. 2). Using an *in vivo* kinetics system, a similar K_m has been reported for the C-20 hydroxylase of the fly *Calliphora stygia*[13]. Chemical identification of β-ecdysone as the product of this putative C-20 hydroxylase was attained by acetylation finger printing of labelled product[3] and ultimately by mass spectrometry of 1.0 µg unlabelled material (m/e 462, 444, 426, 408, 345 and 328).

Table 2 Effect of various co-factors and gases on the oxygenation of α-ecdysone by fat body mitochondrial C-20 hydroxylase

Co-factor	Relative C-20 hydroxylase activity
NADPH	1.0
NADP	0.07
NADH	0.27
NAD	0.01
ATP	0.05
ADP	0.03
NADPH-generating systems:	
Glucose-6-phosphate dehydrogenase	1.0*
Krebs cycle intermediates:	†
Malate	0.13
Malate + NADP	0.59
Fumarate + NADP	0.11
Isocitrate + NADP	0.12
Gases	
Air	1.0
Ar	0.97
CO_2	0.05‡
CO	0.38
N_2	0.95
O_2	0.86

The method for assaying C-20 hydroxylase activity was as in Table 1. A dose response was determined for all cofactors at concentrations from 2.0×10^{-7} to 4.0×10^{-4} M. For NADPH and NADH, C-20 hydroxylase activity was dose dependent with a $V_{max/2}$ for NADPH of 6.0×10^{-6} M. Maximum oxygenation with NADH was not obtained at concentrations up to 4.0×10^{-4} M. For the rest of the cofactors, hydroxylase activity did not increase significantly above background. Gases were introduced to the standard assay system by bubbling at a flow rate of 35 ml min^{-1} for 2 min. Following the introduction of gases and incubation, O_2 was present at a concentration of approximately 60 nmol ml^{-1}, which was 25% of the O_2 concentration of controls incubated in the absence of added gas. Stoichiometrically, this is a 5.4×10^3 excess of O_2 for the C-20 hydroxylation of α-ecdysone and precludes oxygen depletion as an explanation for the observed changes in C-20 hydroxylase activity in these gas studies.

*A glucose-6-phosphate dehydrogenase NADPH-generating system provided maximal C-20 hydroxylase activity at 4.0×10^{-6} M NADPH generated.

†Krebs cycle intermediates (2×10^{-2} M) were used to generate NADPH from exogenous NADP (4×10^{-4} M, equivalent to the NADPH in the hydroxylase assay). The ultimate effect of the Krebs cycle intermediates is apparently to provide an increased reduced cofactor (NADPH) pool for hydroxylase activity, as evidenced by the requirement for NADP with the Krebs cycle intermediates. Succinate, citrate, α-ketoglutarate and oxaloacetate in the presence of NADP did not increase hydroxylase activity above that observed for NADP alone.

‡Low conversion in the presence of CO_2 was probably due to acidification of the assay mixture by CO_2 to pH 6.2, which is below the minimum pH (6.5) for preservation of C-20 hydroxylase activity.

Substrate specificity of the C-20 hydroxylase is at present being assessed using a variety of steroids and ecdysone analogues. Preliminary results suggest that there is a high degree of specificity which depends on the number and position of hydroxyl groups, and more importantly, on the stereochemistry of the AB ring and side chain.

To demonstrate that the mitochondrial α-ecdysone C-20 hydroxylase is a cytochrome P-450 mixed function oxidase, the following criteria were used: dependence on NADPH (using an exogenous NADPH or NADPH generated by a glucose-6-phosphate dehydrogenase system[14] or NADPH generated by Krebs cycle intermediates[15]); inhibition by CO[7,8], metyrapone (Metopiron)[16], aminoglutethimide (Elipten)[16] and p-chloromercuribenzoate[14]; and a CO difference spectrum[17]. The C-20 hydroxylase activity was dependent on NADPH or NADPH generating systems as electron donors, with NADH being only about 25% as effective (Table 2). The C-20 oxygenation of α-ecdysone was efficiently inhibited by CO (Table 2), p-chloromercuribenzoate ($I_{50} = 5.0 \times 10^{-7}$ M), aminoglutethimide ($I_{50} = 1.0 \times 10^{-5}$ M) and metyrapone ($I_{50} = 5.0 \times 10^{-6}$ M). Metyrapone acts as a competitive inhibitor with an apparent K_i of 3.9×10^{-6} M (Fig. 2). The CO difference spectrum obtained for the CO-bound sodium dithionite-reduced mitochondria was similar to those obtained from vertebrates with an absorption maximum at A_{450} (Fig. 3).

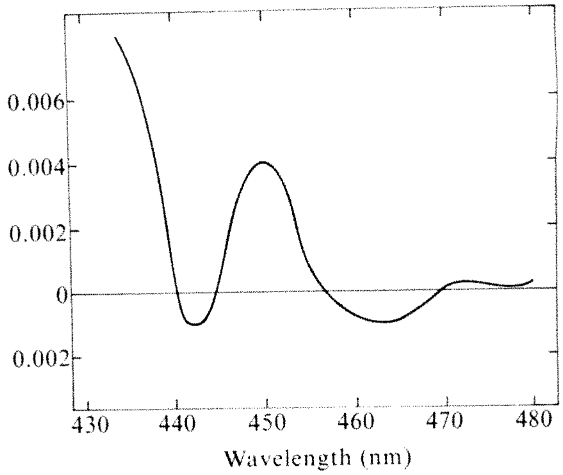

Fig. 3 A CO difference spectrum of sodium dithionite-reduced fat body mitochondria. The sample cell contained a suspension of dithionite-reduced mitochondria saturated with CO, whereas the reference cell contained only dithionite reduced mitochondria. The difference spectrum was obtained using a Cary 14 spectrophotometer equipped with a transmission scatter attachment.

The above studies demonstrate that the α-ecdysone C-20 hydroxylase is located in the insect fat body mitochondria and that cytochrome P-450 is probably the oxygen activator for the oxygenation of α- to β-ecdysone. This is the first report implicating a cytochrome P-450 mixed function oxidase in the oxygenation of steroids in insects, and in arthropods in general.

We thank Dr P. Loach for assistance with the spectral studies, Dr D. Hung for mass spectrometry expertise and Drs D. King and P. Karlson for providing ^{3}H-α-ecdysone. These studies were presented in part at the XV International Congress of Entomology, 19–27 August, 1976. This research was supported by grants from the NIH and the NSF. W. E. Bollenbacher is an NIH postdoctoral fellow.

Potential-dependent transition temperature of ionic channels induced by glutamate in locust muscle

RECENT work has emphasised the important role which the state of the membrane has in the function of its transport and enzyme systems[1,2]. At various synapses the action of transmitter substances is accompanied by 'membrane noise' associated with the opening and closing of ionic channels. Analysis of this noise gives an estimate of the mean conductance and lifetime of the single open channel[3–9]. In locust muscle we have found that the mean lifetime (τ) of channels, activated either by the natural transmitter or by externally-applied glutamate, is prolonged as the temperature is lowered, while the conductance (γ) of the single channel is decreased. The dependence of γ and τ on temperature shows a change in slope at a temperature which itself depends on the membrane potential. These results are possibly due to a potential-dependent phase transition in the membrane around the channel causing an abrupt change in the operation of the gating molecule and conductance-determining portion of the channel.

Distal fibres of the metathoracic extensor tibiae muscle[10] of the locust (*Schistocerca gregaria*) were voltage-clamped using two intracellular microelectrodes. L-glutamate was applied ionophoretically from a micropipette to a junctional site[7,11]. The bathing medium was as previously described and contained increased Mg^{2+} and decreased Ca^{2+} in experiments where the nerve was stimulated. Bath temperature was controlled with a Peltier cooling device and monitored with a thermistor placed near the muscle bundle under investigation. Bath reference electrodes were isolated through agar bridges to reduce temperature-induced junction potentials. Temperature readings were accurate to within ±0.5 °C.

The energy spectrum of the current noise obtained during steady application of glutamate to junctional receptors in locust muscle results from statistical fluctuations in the opening of ionic channels, and agrees well with a first order process which follows the relationship[7]

$$S(f) = \frac{2\gamma\mu_g/\alpha}{1 + (2\pi f/\alpha)^2} \tag{1}$$

characterised by the independent parameters γ and α. Under a specific hypothesis for the operation of the glutamate-sensitive receptor complex[7], similar to that suggested for acetylcholine receptors in vertebrate muscle[3,4,12], γ and α are respectively the conductance and closing rate constant of the single ionic channel. The mean life-time of the open state is given by $\tau = 1/\alpha$.

For a given mean conductance (μ_g) lowering the temperature prolongs the mean life-time (τ) of the open channel (seen as a shift in the cut-off frequency of the noise spectrum) and reduces the variance of the noise, by decreasing the conductance of the single channel (seen as a reduction in the zero frequency asymptote, $S(0)$, of the spectrum). Apart from altering γ and α, changing the temperature did not alter the spectral relationship (equation 1) over the range studied (2–25 °C).

Figure 1 shows the temperature-dependence of γ (the single-channel conductance), and α (the rate constant for channel closing) at a fixed membrane potential. γ and α decrease exponentially with the inverse of the absolute temperature (°K) at all temperatures studied but, at about 6 °C the slope of the

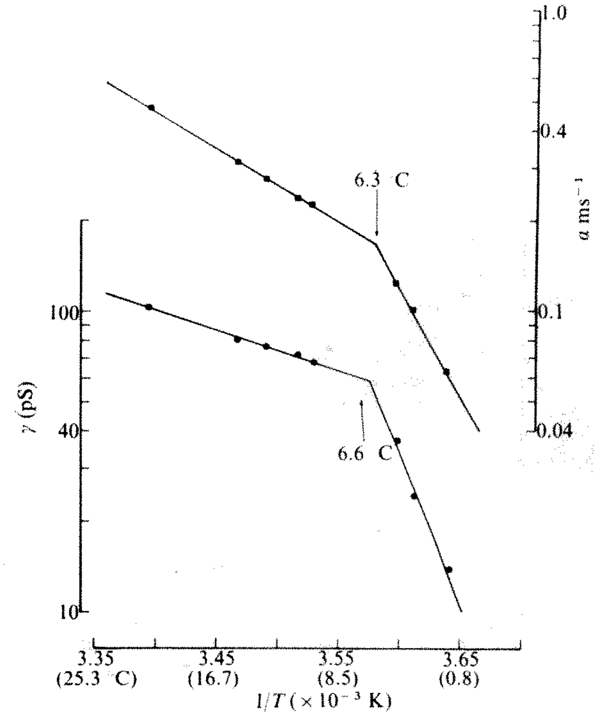

Fig. 1 Temperature dependence of the glutamate-induced single-channel characteristics. The channel closing rate constant (■) α (ms^{-1}) and the single channel conductance (●) γ (pS) are plotted semilogarithmically against T^{-1} (Kelvin). Temperatures in °C are given in parentheses. Values were obtained during steady ionophoretic application of glutamate by fitting the membrane current fluctuation spectra to the relationship in equation (1). Background noise spectra were subtracted before fitting. Transition temperature for α is 6.3 °C and for γ is 6.6 °C, for a membrane potential of −100 mV. The agreement between the data and the solid lines suggests that α and γ behave according to a reaction scheme in which the apparent activation energy increases sharply below the transition temperature. Data is from six voltage-clamped fibres. Each point represents the spectral parameters of the average spectra from 20 noise segments each digitalised at 2,048 Hz in 1,024 point segments over 0.5 s. Spectral estimates were calculated using an F.F.T. algorithm.

relationship changes abruptly. The values for γ and α may be fitted to the relation depicted by the solid lines in Fig. 1, which represent the behaviour expected of first-order rate processes. For α, this hypothesis is governed by the relationship[12]

$$\alpha = \hat{\alpha} e^{-E_\alpha/RT} \quad (2)$$

where E_α is the energy required for movement of the gating molecule where α is constant, T is absolute temperature in °K and R is the gas constant. The lines drawn for α in Fig. 1 show the relationship for $T > 6$ °C, where $\alpha_1 = 1.15\times10^8$ ms^{-1}, $E_{\alpha2} = 11.4$ kcal mol^{-1} and for $T < 6$ °C, $\alpha_2 = 1.37\times10^{25}$ ms^{-1}, $E_{\alpha2} = 33.3$ kcal mol^{-1}.

If the single-channel conductance is envisaged as being determined by the rate of transfer of ions, ν, across an energy barrier, E_γ, in the postsynaptic membrane, then the resulting first order rate process may be represented by

$$\nu = \hat{\nu} e^{E_\gamma/RT} \quad (3)$$

which yields the unitary conductance

$$\gamma = \nu ZF/(V - V_{eq})A \quad (4)$$

where Z is valence, F is Faraday's constant and A is Avogadro's number. The lines drawn for γ in Fig. 1 show the relationship for $T > 6$ °C where $E_{\gamma1} = 6.12$ kcal mol^{-1} and for $T < 6$ °C, $E_{\gamma2} = 46.5$ kcal mol^{-1}. The transition temperature for α is 6.3 °C (at $V_m = -100$ mV) and for γ is 6.6 °C ($V_m = -100$ mV). Transition temperature values for α and γ are practically the same within the accuracy of our measurements.

At acetylcholine receptors in frog muscle[4] and at glutamate receptors in locust muscle[7], the postsynaptic excitatory junctional current (e.j.c.) evoked by nerve stimulation has an exponential decay with a time constant ($\tau_{e.j.c.}$) identical to that which characterises the $1/f^2$ component of the current noise spectrum; $\tau_{e.j.c.} = 1/2\pi f_c = \alpha/2\pi$, where f_c is the half-power frequency of the spectrum. This allowed us to investigate the temperature dependence of α for channels activated by the natural transmitter. This technique was also used to study more fully the behaviour of the rate constant close to the point of transition, and particularly its dependence on membrane potential.

Figure 2 shows a semilogarithmic plot of $\tau_{e.j.c.}^{-1}$ as a function of T^{-1} at two membrane potentials. The relation follows two straight lines at each potential without obvious curvature near the critical temperature. This may suggest a discrete change in a single rate limiting energy barrier rather than a dual process with different temperature dependencies, or a single kinetic scheme in which the activation energy is a continuous function of temperature. The results fit well the relationship $\tau = \tau e^{(E_a + \eta(T))/RT}$, which is predicted from an energy barrier model for the closing of channel gates (unpublished) in which the free energy change of the system is coupled to the electric field through a temperature-dependent dipole (η). Values for the apparent activation energies and transition temperatures are given in Table 1. As is seen in Fig. 2, the transition temperature depends on membrane potential in such a way that depolarisation causes a shift in transition temperature to higher values. Transition temperature seemed to show a linear dependence on membrane potential.

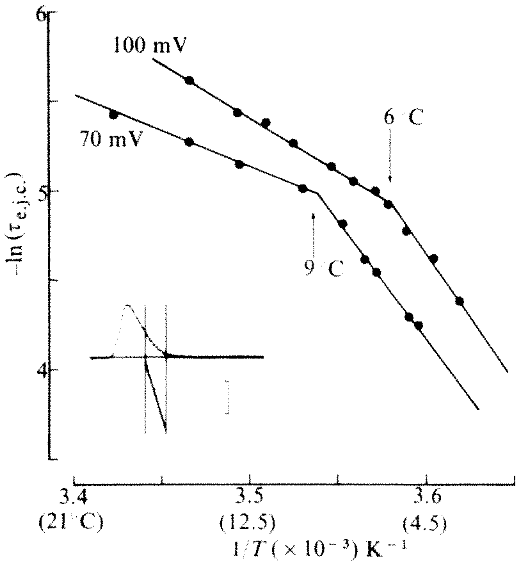

Fig. 2 Arrhenius plot of temperature dependence of the time constant of decay of nerve-evoked e.j.c.s in two muscle fibres clamped at −100 mV and −70 mV respectively. As shown in the inset, digitalised e.j.c.s were plotted semilogarithmically and a least squares line fitted to the decay phase gave $\tau_{e.j.c.}$ (calibration bar 80 nA; e.j.c. is 70 ms full sweep; V_m, 100 mV; T, 20 °C). Each point on the graph represents at least 50 such determinations. In all cases the standard error of the mean is smaller than the symbol. Transition temperatures obtained from the intercepts 6.1 °C at V_m = 100 mV and 9.1 °C at V_m = 70mV. Fibre input resistances were 2.1 MΩ (V_m, 100 mV) and 5.2 MΩ(V_m, 70 mV). Clamp efficiency was better than 99.6% at 0 Hz and better than 90% at 1.6 kHz. Temperatures (°C) are given in parentheses.

We conclude that the apparent activation energies of the rate processes characteristic for the synaptic gate and the conductance-determining portion of the ion channel undergo a discrete change in value at a transition temperature which depends on membrane potential.

One interpretation of the break in the Arrhenius plots shown in Figs 1 and 2, is that it reflects a conformational change in the receptor—and associated ionic channel—similar to that observed in some proteins[13]. Another possibility is that the break is a consequence of a lipid phase transition in the membrane[1,2]. A change in the state of membrane lipids has already been invoked to explain the effects of alcohols on miniature endplate currents in toad muscle[14]. But, the possibility that the fluidity of the lipids associated with the receptors may influence their function, should be considered only as a speculation until direct measurements are made on the nature and state of the lipids surrounding the receptors.

If the break in the temperature dependence of α and γ is due to a lipid phase transition, then several questions arise. For

Table 1 Apparent activation energies (E_{a1}: above transition temperatures; E_{a2}: below transition temperatures) for the rate constant for channel closing α and for the rate constant for the transmembrane flow of ions ν

	Rate constant	V_m (mV)	E_{a1} (kcal mol^{-1})	Q_{10}	E_{a2} (kcal mol^{-1})	Q_{10}	E_{a1}/E_{a2}	Transition temperature (° C)
Glutamate	α	−100	11.4	1.8	33.3	6.3	1/2.9	6.3
	ν	−100	6.1	1.2	46.5	7.2	1/7.6	6.6
Transmitter	α	− 70	8.2	1.7	25.9	5.4	1/3.2	9.1
	α	−100	11.9	2.2	28.1	6.6	1/2.4	6.1

Values are averages based on fitting the relationships $\alpha = \alpha e^{E_a/RT}$ and $\nu = \nu e^{E_\gamma/RT}$ to the data for $\alpha(V_m,T)$ and $\gamma(T)$ respectively. Values obtained in response to glutamate or in response to neurally released transmitter as indicated.

instance, in cell membranes the transition usually occurs over a broad change in temperature and the Arrhenius plot may show two breaks and three segments: one corresponding to the transition range, and one above and one below the transition. Our plots seem to have only two segments. This could indicate that the transition occurs over a narrow range in temperature, perhaps as a result of the close packing and relative immobility of the receptors which may be anchored in the synaptic membrane. Alternatively, the lower end of the transition may not have been reached.

The similarity of the transition temperatures for single channel conductance (γ) and for the rate constant of channel closing (α) may indicate that both processes are affected by the same mechanism. Perhaps the glutamate recognition site of the receptor, and that part of the receptor which contains the main energy barrier for ion translocation, lie close together and penetrate well into the membrane so that both portions may be altered by changes in lipid structure. In embryonic chick muscle[9] and at mammalian endplates[15], a break has been observed in the relationship between temperature and channel conductance, but not in that between temperature and lifetime of the channels induced by acetylcholine. The reason for this apparently different behaviour of glutamate and acetylcholine receptors is not yet clear. Perhaps the recognition site of the acetylcholine receptor lies more in the aqueous external face of the membrane, and relatively distant from the membrane-embedded portion which controls the ionic flux; in which case a lipid phase transition may not exert an important influence on the drug–receptor kinetics.

If the transition we described results from a phase change in the lipid associated with the receptor, then the voltage dependence of the transition could result from a coupling of the membrane electric field to the charge distribution in the lipid component.

Are cell affinity relationships for insect epidermal tissues evidence for combinatorial control?

THE segregation of determined, yet undifferentiated, cells in aggregates consisting of cells from various vertebrate embryonic structures represents a high degree of specificity in cellular recognition[1–3]. Steinberg's differential adhesiveness model[2] has been particularly successful in accounting for this sorting out of cells in terms of differences in their adhesiveness. Although arranged in monolayers, insect epidermal cells seem to behave similarly when their normal spatial organisation is disrupted. The regrouping of disaggregated *Drosophila* imaginal disk cells according to epidermal type and the failure of grafts from one epidermis to form stable contacts with cells of another epidermal tissue have both been attributed to sorting out of unlike cells[4,5]. Yet some insect epidermal cell types fail to segregate completely from one another; even when disaggregated and mixed, cells from genetically marked leg and antenna disks are known to form some integrated patterns[6]. It is possible that different degrees of adhesiveness exist for various combinations of two different epidermal types, the adhesive properties not being uniquely specified for each tissue. With this possibility in mind, exchanges between grafts and hosts of various pupal epithelia of the moth, *Manduca sexta*, were performed. The affinity relationships observed reflected the existence of covert cell surface differences in these epidermal populations whose component cells at the time of grafting are determined but undifferentiated. The findings suggest that the cell surface properties are not tissue type specific but are shared to various degrees by the different epidermal tissues.

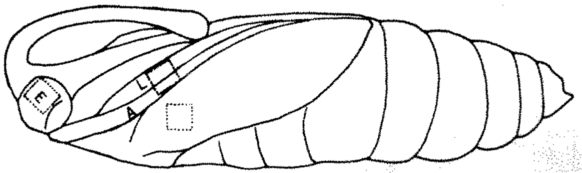

Fig. 1 The tissue regions used for grafting in the study of inter-tissue affinities. Dorsal is to the bottom. Four different epidermal tissues were selected: wing (W), eye (E), antenna (A), and mesothoracic leg (L). The graft sizes varied slightly but were usually 1.5 × 1.5 mm, each consisting of approximately 6,000 cells. All grafts were removed from recently pupated animals (6–15 h after pupation); at this stage the cells showed no evident morphological differences in the light microscope. Because of the proximity of antenna and leg epidermis to each other, these two epithelia were removed and transferred as a single graft unit. In all transpositions (except between leg and antenna) the original orientations of the grafts were retained. In the contralateral exchanges between antenna and leg, which were necessitated by the fact that the two tissues were handled only in combination, the dorsoventral axes of these tissues were reversed without concomitant reversal of their proximo-distal axes. Therefore, the possibility existed that misalignment of the dorsoventral axes of host and graft influenced their mutual affinities. But, in control experiments involving similar contralateral exchanges between either an antennal pair or a leg pair, differences in epidermal properties were never manifested.

Animals for experiments were reared, selected, and treated as described in Nardi and Kafatos[7]. The pupal tissue regions chosen for the study are shown in Fig. 1. Contact between two different tissues was scored in animals just before the time of adult emergence from the pupal cuticle (3 weeks after pupation) and varied from contact involving little or no decrease in original graft perimeter to the formation of completely free, differentiated graft vesicles. By carefully removing the overlying pupal cuticle from the grafting sites, all graft tissues were recovered; otherwise unattached vesicles would have been lost during adult emergence. Only the presence or absence of contact between host and graft was scored, and the results were expressed as fractions of grafts that maintained cell–cell contact with host tissues. Because of the ease in distinguishing free vesicles from attached graft tissues under a dissecting microscope, ambiguities in scoring were avoided. Figure 2 shows typical grafts that were scored as having maintained cell contact with the host.

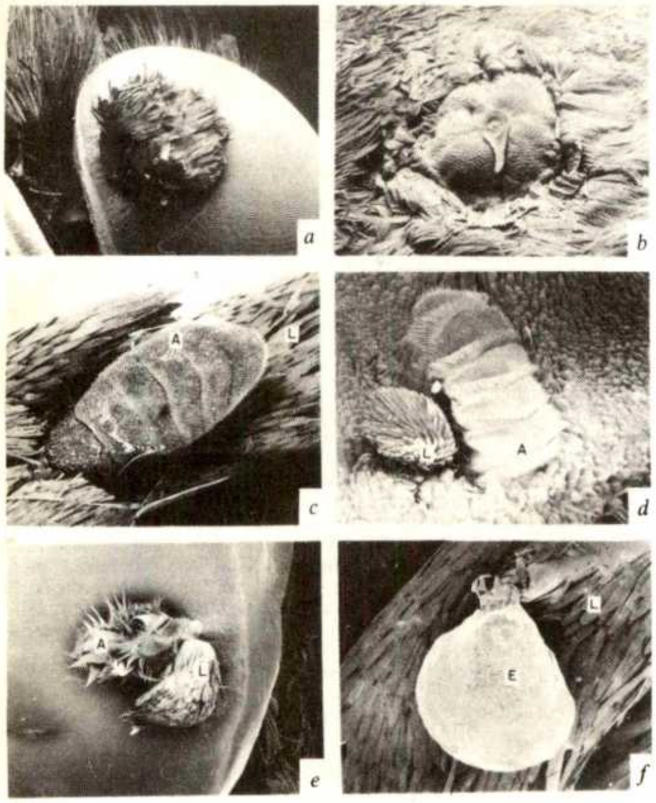

Fig. 2 Scanning electron microscope photographs of representative grafting results. *a*, Extensive contact exists between the wing cells and the eye epidermis (×28.5). *b*, Eye tissue transposed to the wing (×42). *c*, Female antenna (A) tissue adhering to the leg (×63). *d*, Leg (L) tissue and male antenna epidermis (A) tenuously attached to the wing surface (×45). *e*, Male antenna epidermis and leg epidermis grafted to eye. Only the antenna tissue is attached to eye; the leg epidermis is attached to the antenna (×39.5). *f*, An inverted eye vesicle attached to the leg (×120).

No evidence of vesicle formation was found for grafts exchanged within a given epithelium (Table 1); this was true whether grafts were transferred between different positions in the same epidermis or exchanged between corresponding sites of two pupae. Moreover, a particular epithelial tissue shows no consistent tendency either to fail or succeed in establishing contact with different epithelial cell populations. These facts argue against the possibility that the observations reflect grafting artefacts rather than cell surface differences.

Table 1 Fraction of grafts which form stable contacts with host tissues

Graft	Host	No. of exchanges	No. of adhering grafts	Fraction of grafts adhering (affinity value)	Significance level of differences in affinity values for a given exchange between two epidermal types
W	W	34	34	1.0	—
L	L	34	34	1.0	—
A	A	34	34	1.0	—
E	E	34	34	1.0	—
W	L	35	11	0.3	$P<0.03$
L	W	35	21	0.6	
W	A	35	14	0.4	$P<0.01$
A	W	35	32	0.9	
W	E	35	8	0.2	$P<0.02$
E	W	35	19	0.5	
L	A	46	17	0.4	$P<0.01$
A	L	46	46	1.0	
E	L	33	1	0.0	$P>0.10$
L	E	33	1	0.0	
E	A	33	7	0.2	$P<0.01$
A	E	33	23	0.7	

Several notable features emerge from Table 1. First, there is considerable disparity in affinities. For example, values range between the extreme values of 1.0 for antennal grafts transposed to leg epidermis and 0.0 for leg epidermis transposed to eye tissue ($P < 0.01$). A given graft does not show the same affinity for all the host sites examined. This is clear for exchanges of L→E and L→W, these values being 0.0 and 0.6, respectively ($P < 0.01$). Second, in a reciprocal exchange the affinity value is a function of which tissue is the graft and which is the host. For most of the pairs listed, the two affinity measures are not equivalent (with the exception of the eye, leg exchanges). This disparity is well illustrated by a comparison of the 0.4 affinity value for L→A to the value of 1.0 for A→L ($P < 0.01$). Other reciprocal exchanges show statistically significant differences in affinity values. Third, evidently no correlation exists between affinity and spatial arrangement of *Manduca* tissues. The distance separating the eye from the leg is no greater than that separating the eye from the wing region; yet the fractional values for the E→L and E→W exchanges differ by almost a factor of ten.

The affinity asymmetry for two given tissues is most readily accounted for by a model which deals with pairs of tissues that are either at configurational equilibrium or that are approaching it through minimisation of their surface free energies[2,7]. In applying the model to an exchange between A and B tissues whose cells are arranged in monolayers, B graft cells, after a given time period, will show more extensive contact with A host cells than that displayed by A grafts with B host tissue provided that certain A–B relationships hold true, that is, the cohesiveness of A cells exceeds the cohesiveness of B cells. This situation is analogous to the asymmetrical, albeit three-dimensional, interaction of two immiscible liquids A and B, one of which exists either as a liquid drop or a film on the surface of a liquid substrate. A drop of A will form as long as the sum of the surface energy for A and the surface energy of the A–B interface exceeds that for substrate B; but if the surface energy of the substrate A exceeds the total surface energy for drop B and the A–B interface, then B augments its contact with the substrate. In speaking of surface energy for monolayers of cells, we are dealing with the energy for those lateral cell surfaces which establish contact with adjacent cells. This energy is a reflection of the cells' cohesiveness.

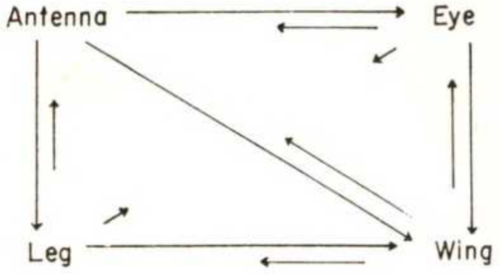

Fig. 3 Mutual affinities of various *Manduca* epidermal tissues. The unidirectional arrows between two epithelia point from the graft to the host tissue; and the relative magnitudes of the arrows for a given exchange reflect relative affinities for that exchange.

According to the combinatorial model of Kauffman which deals with the phenomena of determination and transdetermination in *Drosophila*, the global directionality that is manifested by the transdetermination pathway and the affinity relationships in Fig. 3 (that is, the prevailing orientation for every exchange is towards wing) may indicate the existence of underlying bistable control systems[8]. Another model involving binary developmental decisions—the selector gene model—is based on genetic analysis of *Drosophila* development and was independently developed by Garcia-Bellido[9]. In this combinatorial model, selector genes comprise that set of genes controlling developmental pathways and determination. Of major relevance to the study discussed in this report is that work with one such gene, the wild-type allele of the *engrailed* locus, has suggested that the activity of selector genes supplies cells with distinctive surface labels that govern cellular recognition[10].

Although the nature of the relationship between determination and the mutual adhesiveness of different epidermal cells remains obscure, the striking correspondence between these two phenomena suggests that, regardless of the location of the determinative factors, the cell surface properties are probably closely associated with decisions involving cell determination.

Control of induction of tubulin synthesis in *Chlamydomonas reinhardi*

REMOVAL of the flagella from the biflagellate alga *Chlamydomonas reinhardi* results in the rapid production of new flagella[1–3]. Flagellar regeneration is 80–85% complete within 60 min (Fig. 1). Indirect evidence obtained from *in vitro* translation of polyribosomes and mRNA from deflagellated gametes[1] has indicated that flagellar regeneration is accompanied by a strong but transient induction of tubulin synthesis. Kinetic analysis showed that tubulin mRNA could be detected in polyribosomes in as little as 15 min after deflagellation. Since the cytoplasm contains a reserve of tubulin of sufficient size to supply at least one-third to one-half of the tubulin subunits required for flagellar reassembly[1,3], the rapid initiation of tubulin synthesis following deflagellation suggested the existence of a highly sensitive system for detecting and responding to the cell's anticipated need for additional tubulin. As an approach to seeking such a mechanism, we have carried out studies to determine if the depletion of tubulin reserves during flagellar outgrowth might provide the signal for the induction of tubulin synthesis. We present here two types of experimental evidence which clearly demonstrate that the induction of tubulin synthesis is independent of the utilisation of tubulin reserves during flagellar regeneration.

Comparison of the spectrum of proteins produced by control and deflagellated gametes during a 30 min pulse label with $^{35}S\text{-}H_2SO_4$ shows that deflagellation results in a marked induction of the α (56,000 molecular weight) and β (53,000 molecular weight) subunits of tubulin (see tracks 2 and 6, Fig. 2). Chloramphenicol is added during *in vivo* labelling to prevent the synthesis of the 55,000 molecular weight subunit of ribulose bisphosphate carboxylase (tracks 3 and 4) that would otherwise interfere with the analysis of tubulin synthesis (tracks 1 and 5 compared with 2 and 6). The magnitude of tubulin induction following deflagellation is indicated by densitometric analysis of the radioautographs presented in Fig. 3 (tracks 1–4). In the time intervals 15–45 min, 45–75 min, 105–135 min and 165–195 min, tubulin synthesis accounts for 18.1, 14.5, 7.7 and 3.2 of total cellular protein synthesis (4% has been subtracted from each value to compensate for 'background' incorporation in the 53–56,000 molecular weight region of gels containing proteins synthesised by non-deflagellated cells).

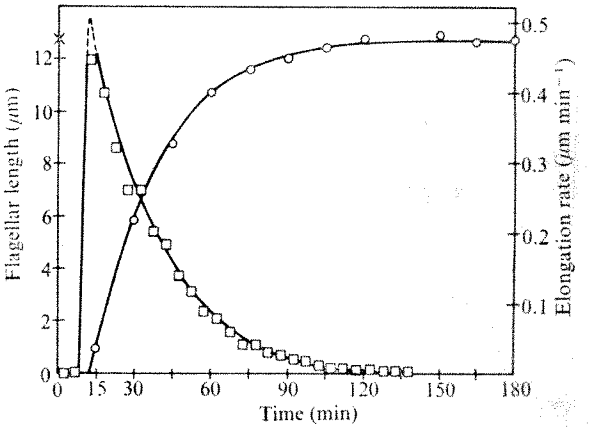

Fig. 1 Flagellar regeneration in gametes of *C. reinhardi*. Gametic cells were deflagellated by vigorously stirring cells at *p*H 4.7 for 1 min and then raising the *p*H of the medium to 7.0 (ref. 3). At various times after deflagellation, cells were fixed with 1% glutaraldehyde and 10 mM potassium phosphate (*p*H 6.8), and flagellar length measured as described previously[1]. ×, Initial flagellar length; ○, flagellar length; □, rate of flagellar elongation. For preparation of gametic cultures, synchronously grown vegetative cells of strain 137c near saturation density were transferred to a nitrogen deficient media, either medium 2-N (ref. 1) or medium 2-N without sulphate (designated medium V) in which an equivalent level of $MgCl_2$ was substituted for $MgSO_4$. If gametes were formed by overnight incubation in medium 2-N, they were rinsed and re-suspended in medium V 1 h before deflagellation (or before labelling with $^{35}S\text{-}H_2SO_4$).

The above *in vivo* labelling experiments provide a direct demonstration of the rapid and extensive nature of tubulin induction following flagellar excision. Additional experiments (not presented) have shown that the initiation of tubulin synthesis occurs between 12 and 15 min after deflagellation. Thus, if *de novo* synthesis of tubulin mRNA is required for tubulin induction, as suggested by the observation that tubulin mRNA is not detectable in non-deflagellated cells[1], then the time requirements for mRNA transcription, processing and transport[10], dictate that the signals required for the activation of tubulin genes must be generated by reactions intimately associated with the deflagellation event. Since flagellar regeneration is not observed until 10–12 min after deflagellation (Fig. 1), the kinetic data suggest that utilisation of tubulin subunits for flagellar outgrowth cannot serve as a feedback signal for the induction of tubulin synthesis. As a further, more direct, test of this question, we have treated cells with a variety of compounds that block flagellar regeneration to determine if these treatments have any effect on tubulin induction. Results presented in Fig. 3 show that treatment of cells with 1 mM isobutylmethylxanthine (IBMX) either 15 min before deflagellation (tracks 5–8) or immediately after deflagellation (tracks 9–12) has no effect on the early phases of tubulin induction even though IBMX, like other methylxanthines[11,12], completely blocks flagellar outgrowth. Treatment of deflagellated cells with colchicine, chloro-isopropyl-*n*-phenylcarbamate, 50 mM potassium phosphate (*p*H 6.8) and other agents that prevent flagellar regeneration, provide nearly identical results to those obtained with IBMX (not shown). These findings provide clear evidence that utilisation of tubulin reserves for flagellar outgrowth cannot serve as a signal for the initiation of tubulin synthesis.

Finally, it may be noted that although intracellular tubulin concentrations do not seem to control the early phases of tubulin synthesis, indirect evidence indicates that increasing reserve levels may govern tubulin production during the later stages of flagellar regeneration. A comparison of data in Figs 1 and 3 shows that relatively high levels of tubulin production continue well beyond the time when flagellar outgrowth is essentially complete and therefore suggests that tubulin reserves accumulate during the late stages of regeneration.

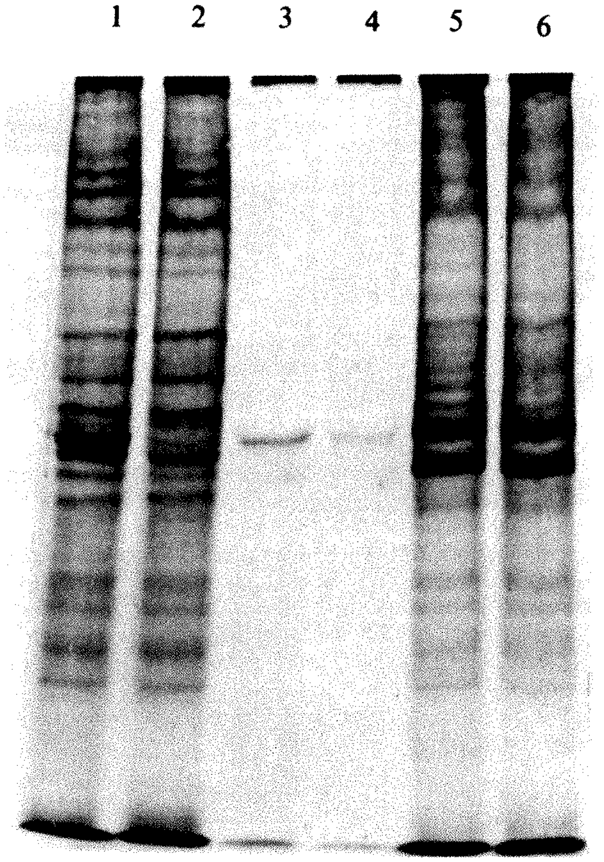

Fig. 2 Autoradiographs of SDS–polyacrylamide gels containing *in vivo* labelled proteins from deflagellated *Chlamydomonas* gametes. Cells were labelled with $^{35}S-H_2SO_4$ using modifications of procedures developed by Lefebvre and Rosenbaum (personal communication) and other laboratories[5–8]. Approximately 10^7 sulphate-starved cells in 0.5 ml were labelled for 30 min in 100 μCi carrier-free $^{35}S-H_2SO_4$. Non-deflagellated cells were incubated without protein synthesis inhibitors (track 1); with 100 μg ml^{-1} chloramphenicol to inhibit chloroplastic protein synthesis (track 2); with 10 μg ml^{-1} cycloheximide (track 3) or with 10^{-4} M 2-(4-methyl-2,6-dinitroanilino)-*N*-methylpropionamide (ref. 9, MDMP) (track 4) to inhibit protein synthesis by 80S cytoplasmic ribosomes. Cells deflagellated by the *p*H shock method were incubated for 15–45 min after deflagellation in the absence (track 5) or presence of chloramphenicol (track 6). After incubation, a 5-μl aliquot of each sample was taken for hot TCA determination of ^{35}S incorporation into protein[1]. The remainder of each sample was precipitated with 5 ml acetone. For analysis on SDS–polyacrylamide gels, the acetone powder from each sample (which can be stored indefinitely) was dissolved in 2% SDS, 5% mercaptoethanol, 10% glycerol, 60 mM tris (*p*H 7.6), and an aliquot with 2 × 10^6 c.p.m. (except for tracks 3 and 4) electrophoresed on 9% SDS–polyacrylamide gels as described previously[1]. Autoradiographic exposure of the dried gel was for 12 h.

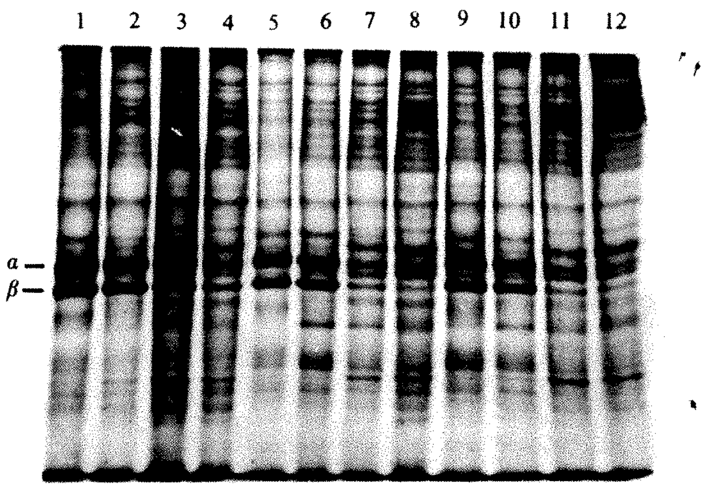

Fig. 3 Tubulin synthesis following deflagellation of control or IBMX-treated cells. Deflagellated cells were labelled for 30-min intervals at 15–45, 45–75, 105–135 and 165–195 min after deflagellation in the absence (tracks 1–4) and presence of 10^{-3}M IBMX given either 15 min before deflagellation (tracks 5–8) or immediately after deflagellation (tracks 9–12). Labelling with $^{35}S-H_2SO_4$ in the presence of chloroamphenicol was as described in Fig. 2.

Thus, the earlier than normal shut off of tubulin synthesis in IBMX-treated cells (Fig. 3, tracks 5–12 compared with 1–4) suggests that a feedback mechanism responsive to increasing tubulin concentrations, could be responsible for the ultimate repression of tubulin synthesis during flagellar regeneration.

Erratum

In 'Stability of Lotka–Volterra systems' (*Nature*, **264**, 381; 1976) the name of the co-author, J. S. Semura, was omitted.

Nature Index and Binders

The complete **Index** for 1976 is available, price £2.50 (UK), US$5.00 (Rest of World). Copies of the 1975 index are still on sale, price £2.25 (UK), US$5.00 (Rest of World).

Binders for the journal are also available at £8.00 (UK), US$16.00 (Rest of World) for three: a year of *Nature* fits into three binders.

All prices include postage. Payment may be made in any currency at the prevailing exchange rate. Orders should be sent, accompanied by remittance, to Macmillan Journals Ltd, Brunel Road, Basingstoke, Hampshire, RG21 2XS, England.

matters arising

Geomagnetism and climate

FAIRBRIDGE[1] correlates the Gothenburg geomagnetic excursion (about 13,500 yr BP) with climatic changes associated with the North American glacial record, eustatic changes in sea level, and changes in rainfall and river discharge in the Nile Valley. Such a correlation is interesting considering the possible resulting climatic effects as suggested by Harrison and Prospero[2]. But, Fairbridge in presenting his case ignores the cyclical nature of the continental and oceanic climatic histories. The Holocene, viewed as a whole, is characterised by alternating intervals of glacial advance and retreats. When viewed in this way the correlation of the Gothenburg geomagnetic excusion with a small segment of the climatic history of the earth is hardly justified. Two examples illustrate the danger involved in this kind of correlation. Denton and Karlen[3], from an examination of ^{14}C dates on glacial termini, show that the dates of glacial maxima peak at 200–300, 2,800 and 5,300 yr BP which suggests a recurrence of major glaciers every 2,500 yr. Extrapolating backwards in time, this pattern suggests glacial advances peaking at about 7,800, 10,300, 12,800 and 15,300 yr BP. The Gothenburg excursion corresponds to the time of the Port Huron advance (12,700 to 13,000 yr BP), and/or the Cary/Port Huron interstadial (about 13,300 to 14,000 yr BP), and is no way a unique event when the whole record is viewed. The single correlation of geomagnetic and climatic events at 13,500 yr BP fails to explain similar climatic changes occurring with some regular frequency over the whole Holocene.

In the same way, Fairbridge cites the oxygen isotope record of the Greenland Ice Core in support of his hypothesis. He presents, however, only a small time interval of this record. The isotope record shows a long term climatic trend from 14,000 to 10,000 BP superimposed on which are major oscillations (ref. 4). Given the nature of this climatic record, the correlation of geomagnetic changes and climate at 13,500 yr BP seems purely coincidental.

Finally, it may be suggested that the oceans might provide a reasonable source of material from which a correlation of geomagnetic and climatic changes may be recognised. The oxygen isotope record of foraminifera from deep-sea cores in the Gulf of Mexico, for example, record a major influx of freshwater between 15,000 and 12,000 yr BP[5]. This resulted from the deglaciation of the Laurentide Ice Sheet and subsequent drainage through the Mississippi River Valley. Its correlation in time with the Gothenburg geomagnetic excursion seems pure chance when one examines the ^{18}O record of deep-sea cores throughout the ocean. From such data[6] one is unable to find any major climatic event over the interval of time in question (11–14,000 yr BP).

Thus while the correlation between geomagnetism and climate is interesting, there is no evidence to support it. The main difficulty with the data given by Fairbridge is that it fails to recognise the cyclical nature of the Holocene Climatic record. While many forcing functions may drive it, the case for geomagnetism as a driving mechanism is yet to be made.

FAIRBRIDGE REPLIES—Hecht insists that I have ignored cycles in climatic history, but this is not so. Three major systems are identifiable: (1) the 200–250-Myr cycle (possibly galactic); (2) the 20,000–100,000-yr Milankovitch cycles (planetary, orbits); and (3) the 11-yr (plus multiples) solar radiation cycle. Each is exogenetic. In contrast, the terrestrial response is greatly dependent on variable palaeogeography—an endogenetic control.

Hecht refers to the excellent glacial chronology of Denton and Karlen. I have made use of it in a paper entitled: 'An 8,000-yr palaeoclimatic record of the 'Double Hale' 45-yr Solar Cycle'[1]. The major coolings on the other hand fall closer to 850-yr intervals, but I do not yet have a convincing casual correlation to offer. The variability does not at present justify Hecht's extrapolations.

In my Fig. 1, covering only the 'small interval' of 8,000 yr, I did not suppress evidence of other oscillations, but merely tried to stress the coincidence of the Gothenburg Event with the largest of them. There still remains a 'chicken-and-egg' problem. The timing of the Gothenburg reversal (closer to 12,500 BP, according to Mörner, personal communications) puts it half-way through the last deglacial phase and thus suggests it was triggered by the massive asymmetric glacial unloading–loading. The latter was catastrophically rapid in geological terms. Thus a general exogenetic global warming trend might trigger an endogenetic geomagnetic phenomenon that in turn introduced a brief cooling. Hecht is right to look at oceanic records, but not for oscillations of only a few centuries. For this information we need carefully analysed cores from lakes where rapid sediment accumulation is taking place.

Palaeomagnetic stratigraphy of the Koobi Fora Formation, east of Lake Turkana (Lake Rudolf), Kenya

IN their recent article on the magnetostratigraphy of the Koobi Fora Formation of northern Kenya, Hillhouse *et al.*[1] noted that amendments to published correlations of the Koobi Fora stratigraphy were desirable but were unable to take this into account in the evaluation of their results. They noted that alternative dates were now available for the KBS Tuff but did not pursue the inference that if one published ^{40}Ar/^{39}Ar date was questionable, others might be similarly suspect. Some of their statements concerning the geographic location of tuffaceous outcrops were misleading.

An important offshoot from detailed investigation of the evolution of African Plio-Pleistocene Suidae has been the acquisition of correlative information of value both within the Koobi Fora region and between this and other African sites of similar age (J. M. Harris and T. D. White, in preparation, ref. 7). Suid correlative evidence suggests, for example, that the 'Tulu Bor' Tuff of Koobi Fora Area 102 (102/T.IV) is in disagreement with Cerling *et al.*[2], clearly younger than the type Tulu Bor Tuff of Area 129

(129/T.II) or undoubted correlativse (116/T.I, 117/T.III) and is probably of similar age to the type KBS Tuff (105/T.II). A second significant fact to emerge is that the suid fauna from immediately subjacent or superjacent to the Tulu Bor Tuff is evolutionarily equivalent to that from the upper part of Shungura Member B at Omo. A third, equally important, consideration is the apparent absence from the Koobi Fora region of fossiliferous sediments yielding faunas equivalent to those from Shungura Members C–E. It is important also to remember that very few fossiliferous sequences from the Koobi Fora region can be shown to represent other than short time spans and that former lithologic correlations between geographically widely separated areas have to be treated cautiously.

It seems reasonably clear from available vertebrate evidence that the Tulu Bor Tuff is not, in terms of conventional radiometric dates, as old as 3.18 Myr (the date obtained for 116/T.I; ref. 3) and that the normal palaeomagnetic interval observed in that part of the sequence incorporating the Tulu Bor Tuff is probably that separating the Kaena and Mammoth events. Faunal evidence suggests interpretation 2 of Hillhouse *et al.* (Fig. 5 of ref. 1) is strongly to be preferred over interpretation 1. There is no need to postulate secondary magnetisation for the early part of the Area 102 succession (Fig. 4, ref. 1)—the observed polarity being consistent with faunal evidence that this part of the succession is equivalent in age to the normal sequence found immediately below and above the KBS Tuff. The suid faunas from the upper part of the Lower Member of the Koobi Fora Formation are evolutionarily equivalent to those from Omo Shungura Member G and Olduvai Bed I. The conventional K/Ar determination of Curtis *et al.*[4] for the KBS Tuff and other tuffs from the upper part of the Lower Member agree with widely accepted conventional K/Ar dates for Shungura Member G and Olduvai Bed I. It is possible that ^{40}Ar/^{39}Ar step heating methods and fission-track determinations that provide an age of 2.4 Myr for the KBS Tuff (and correlates)[5,6] are better chronometric measures—in which case suid evidence suggests that accepted ages for Shungura Member and Olduvai Bed I are too young by about half a million years. These alternative hypotheses require further research.

References by Hillhouse *et al.*[1] to the 'KBS Tuff' of Area 10 and magnetostratigraphic sections from the Tulu Bor Tuff to the 'KBS Tuff' in Area 131 need correction. Area 10 boundaries were redefined in 1974 and the 'KBS Tuff' referred to by Curtis *et al.*[4] is to be found in Area 12 (12/T.II). The Tulu Bor does not crop out in Area 131. It is present in the closely adjacent Area 129 but here, as at other Koobi Fora localities, faunal evidence indicates an appreciable hiatus (equivalent to Shungura Members C–E) between the Tulu Bor and superjacent (KBS = 129/T.IV) tuff. Moreover, to place data from Area 15 and Area 129 in the same magnetostratigraphic column (Fig. 4, ref. 1) implies firm lithostratigraphic correlation between two areas separated by several kilometres of dense bush cover. It implies also a measure of confidence in this correlation that is not shared by all the participants in the Koobi Fora Research Project.

[7] White, T. D. & Harris, J. M. *Science* (in the press).

HILLHOUSE REPLIES—I thank J. M. Harris for reporting some important new developments concerning the fossil Suidae of the Koobi Fora Formation. These previously unpublished results suggest, as he points out, that a more refined interpretation of the magnetostratigraphy is now possible. As outlined by Harris, the faunal evidence apparently supports interpretation 2 of the magnetostratigraphy presented by Hillhouse *et al.*[1] (Fig. 5), but amendments to interpretation 2 are called for. For example, the normal polarity zone that includes the Tulu Bor Tuff can be correlated with the normal interval (2.92–2.99 Myr) separating the Mammoth and Kaena events, and should not be assigned to the end of the Gauss normal epoch (2.41–2.84 Myr) as in interpretation 2. Also, the absence from the Koobi Fora region of fossil faunas equivalent to those from Shungura Members C–E[2] suggests that sediments representing the upper half of the Gauss normal epoch and the lower part of the Matuyama reversed epoch are not present in the Koobi Fora Formation. The adoption of this amended interpretation depends on the strength of the evidence from the fossil Suidae weighed against radiometric dating and palaeontological data from a diverse selection of fauna. We eagerly await publication of Harris's results so the matter can be openly evaluated by geologists and palaeontologists.

Harris is correct in pointing out that because of the 1974 redefinition of area boundaries the 'KBS Tuff' referred to by Curtis *et al.*[3] and by us is now in area 12. As Harris points out, the Tulu Bor does not crop out in area 131. In our Fig. 3 of ref. 1 we emphasised this by not showing the tuff in the stratigraphic column and by stating in the caption, 'The Tulu Bor Tuff is believed to be located approximately 6 m below the base of this section.' This statement was based on Fig. 2 of Leakey[4], which infers the location of the Tulu Bor in area 131. Concerning the observation that the results from areas 15 and 129 are not from the same magnetostratigraphic column, Harris may have missed our comment, " 'Area 129' column is a composite: the upper portion was from area 129, the lower from the adjoining area 15." Finally, we note that Harris's comment that there is no need to postulate secondary magnetisation for the early part of the area 102 succession is in accord with the following statement in our article: "Identities of tuffs are unknown in the lower portion of area 102 column, so we can no longer assume that this section was overprinted with normal polarity."

Maya dates AD 352-1296

PLANETARY conjunctions, in my recent article[1], were used to fix the floating chronology of the Classic Maya codices and stelae. Many planetary configurations, however, repeat themselves after 59.1 yr so that multiple solutions are possible. I first supposed as a limiting condition that the conventional (Goodman–Martinez–Thompson) dates were in error by not more than 30,000 d, so postponing investigation of a possible solution 1,541 days beyond that limit. I found that an adjustment by 27.3 yr brought the planetary cycle into phase, and the adjacent solution 59.1 yr or 21,574 d greater was not fully investigated. Either solution would fit the conjunctions of AD 650/3, 709/11 and 770. My present work[2], has shown that it was my first solution that was spurious: 615,824 d must now be added to all Mayan Day Numbers to get Julian dates, and 59 yr 24 ± 1 d must be added to the Maya dates in my previous[1, 3] articles. This is 86.4 (86 yr 4 months and about 3 d) yr or 31,541 d greater than the conventional dates.

reviews

Science as a never-ending quest

J. R. Ravetz

The Nature of Science: The History of Science in Western Culture Since 1600. By David Knight. Pp. 215. (André Deutsch: London, 1977.) £4.95.

In comparison with many other disciplines studying human behaviour, the history of science is quite peaceful and self-confident. Although divergences of approach have always existed, they have never polarised the whole field. The present book represents a considerable shift in the consensus of what the history of science is all about, and yet it is done in a relaxed, matter-of-fact way, totally devoid of programmatic pronouncements.

What David Knight argues, in *The Nature of Science*, is that it lies as much in the activity of research and its context, as in the results we accept as valid. The supposed 'hard core' of objective facts, which could be studied on their own by philosophers and historians, is now blended into the matrix —social and intellectual—of scientific work.

In order to exhibit this view of science, David Knight must approach history in an unorthodox way. Instead of treating 'periods' in chronological sequence, he uses 'themes'. We have a progression, from the more philosophical ("Science as a Complex Activity", and ". . . as Explanation"), to the more social, linking science to its community, and discussing careers, Government and utility. The bridge-section is on "Science and Not Science".

It is very refreshing for a person familiar with the history of science to see the materials sorted in this way. But this arrangement has its costs, most notably in the loss of a chronological sense for the whole story.

The general literary style is relaxed and conversational. The book makes enjoyable reading, but the shape of events in history becomes quite blurred as the narrative slides from one topic to another.

The history that is told in such a way, especially in a small book covering such a wide range, inevitably becomes a personal statement. The materials reflect the author's own interests; here, social and institutional aspects of English science absorb much space. Also, the text is liberally sprinkled with the author's own generalisations and morals. They are recognisable as such, and fit with Dr Knight's commitment to the view that history, like natural science, is a never-ending quest, best not left exclusively with professionals.

Everyone will find fault or favour with his/her own selection of wisdom. I am intrigued by the suggestion that eighteenth-century chemistry was hindered by the Newtonian orthodoxy; this is a far cry from the classic ridicule of 'phlogiston' as the nonsense theory that awaited overthrow by Lavoisier. Some throwaway statements have rather strong implications; to say that conservatives were "naturally enough often right in resisting innovations", opens up new and challenging perspectives on the history of scientific revolutions and indeed on the methodology of science.

So here is a book to be enjoyed rather than dissected; a very useful introduction to a growing new historiography of science. ☐

J. R. Ravetz is Reader in the History and Philosophy of Science at the University of Leeds, UK.

Genetic expression in plants

Molecular Aspects of Gene Expression in Plants. Edited by J. A. Bryant, Pp. 338. (Academic: London, New York and San Francisco, 1977.) £9.60; $21.

This seven-chapter volume has been compiled by four authors, one of whom is the editor. Together they have many years experience with plant nucleic acids, and they have pooled their joint approaches and expertise to produce an overall view in what the dust cover calls "the first book to deal specifically with gene expression in plants".

The first half is a mine of basic information on the properties and functions of DNA, RNA and proteins in cells, and freely uses information from non-plant sources. The first chapter on nuclear DNA deals effectively with the extraction and properties of DNA, the structure of chromosomes and the modifications and variations that can occur in the genome following synthesis and turnover of DNA *in vivo*. Bryant has done a service in confining the term "nucleohistone" for the DNA–histone complex and "chromatin" for the DNA–histone–acidic protein complex throughout the volume. Although the classification given for histones is the "f" nomenclature, it would have been helpful to undergraduate readers if the "H" nomenclature, which they will surely encounter in the literature, had been included. Nucleosomes receive brief mention only, and although buoyant density fractionations of DNA are discussed, the use of sucrose density fractionations is not.

The chapter on RNA structure and metabolism provides a lucid account of the different classes of RNA, outlining their separation and function as intermediates for the translation of genetic information in protein synthesis. Considerable space is given to the topic of precursor RNA molecules and their processing to ribosomal RNA in both prokaryotic and eukaryotic plants. The possible role of tRNA molecules and the stability and function of mRNA are discussed in relation to well studied examples of the control of transcriptional and translational events in plants.

There follows a straightforward account of the translation steps in protein synthesis with frequent comparisons with bacterial and mammalian systems. Most of the plant information has been gleaned from the extensive work on germinating seeds and protein-synthesising cell-free systems from wheat-germ. Attention has properly been drawn to the gaps in our knowledge for plants. The diagrams and schemes are somewhat repetitious, but the points are very clearly made.

A useful chapter is devoted to gene expression in chloroplasts and mitochondria, to include the basis of their role in cytoplasmic inheritance and the degree of their developmental autonomy. The nature and replication of chloroplast DNA, the transcription of RNA and the assembly of chloroplast proteins (particularly fraction I protein), are presented in an interesting way. The section dealing with mitochondria is brief, but sets out present knowledge of their DNA structure and RNA transcription products, together with the meagre information on their protein synthesis.

The factors linking DNA replication with cell division are treated at length in a wide-ranging and well presented chapter on the cell cycle. Attention is focussed on patterns of nuclear RNA and cytoplasmic protein synthesis and the modifications in chromatin that occur through the different phases of the cycle. Changes in enzyme activities that accompany these cyclic events are well presented. Attempts to isolate control factors in mitosis in plants are described and the role of cyclic AMP, though mentioned, is properly treated with caution. The overall information is neatly summarised and the reader will appreciate the comprehensive diagrammatic presentation of the known regulatory events occurring through the cell cycle of many eukaryotic and prokaryotic types, together with the leads into hormonal and nutrient gradients that can turn on and turn off division in plant cells. Although to some extent the conditions that trip the switches are known, the reader will learn that the operating mechanisms for the switching systems are little understood.

The chapter dealing with molecular aspects of differentiation rests uneasily within this volume, for although it describes in detail the ultrastructural morphogenesis of certain cell types it is not concerned directly with the mechanism of gene expression. It includes, however, a useful and well reasoned survey of transcriptional, translational and post-translational control in protein synthesis.

In the final chapter on plant growth substances we learn that the term "plant hormone" is going out of usage (which I doubt) and that these regulatory substances are the keys to our understanding of differentiation and organisation (with which I concur). Two examples of altered gene expression are considered in detail. One, the control by gibberellic and abscisic acids of the synthesis and secretion of hydrolytic enzymes (especially α-amylase) in barley aleurone cells, and secondly, the role of auxin in the control of cellulases during cell expansion. These aspects of differentiation are well integrated with the earlier chapters on the involvement of nucleic acids and proteins, and include discussion of the conclusions that may be drawn from hormone-modified changes in incorporation and enzymic activity studies.

Taken as a whole, the content of the book is stimulating and very readable. The bibliography and reference system are excellent, and the illustrations and tables have been carefully selected to be simple and instructive. This book is timely and relevant, and will be much used by those seeking information on genetic expression in plants. ☐

Daphne J. Osborne

Peasants to tractor drivers

Cognitive Development: Its Cultural and Social Foundations. By A. R. Luria. Pp. xvi+175. (Harvard University: Cambridge, Massachusetts, 1976.) £9.40.

THIS book reports a pioneering study done in the early 1930s by the gifted Russian psychologist, Luria, to determine the impact of collectivisation, literacy, and newly introduced technology on the peasants of remote Uzbekistan and Kirghizia. It looks for the impact on the cognitive and intellectual processes of those affected: their perception, categorising, reasoning, and self-image, in the conviction that these processes are not simply biologically given but are shaped by cultural–historical processes—a view now widely shared by Marxist and Western psychologists alike, though by no means so in the 1930s. Interestingly enough, the work did not see the light of day in book form in Russia until 1974, its publication having been 'discouraged' as disrespectful of minority group sensibilities when the results were first reported at a time when official Soviet policy was strongly directed toward the integration of minority nationalities, shades of the American experience in the late 1960s with respect to the Blacks in the United States.

The point of view of the book is 'developmental' in the sense that the experience of schooling and modern technological 'collective' life is seen as 'completing' the stages of mental development of illiterate peasants, whatever the age at which they were exposed to the new influences. Although the methods used were 'clinical–experimental' procedures, involving various kinds of sorting and reasoning tests followed up by probing interviews to get at the basic reasons for subjects operating as they did, the results are quite clear at the factual level. Illiterate peasants tend to be much more concrete, function bound, 'complexive' (in the sense of thinking thematically rather than syllogistically), and tied to immediate experience than are their comperes who had been exposed to schooling and the cooperative–technical ways of the collective farm. Luria characterises the advance as 'the leap from the sensory to the rational.' Even with respect to characterising themselves, the illiterate peasants have great difficulty achieving detachment, seeming quite unable to characterise personal traits in a fashion free from functions and duties: they are more situation bound than their literate brothers.

The issue that the book poses is one of interpretation. Granted that 'cultural–historical' factors are important, is it a question of different intellectual powers being available to the two groups on the basis of experience, or is it rather the ways in which human beings, using the same underlying powers, adapt intellectually to their circumstances? An example from the test of syllogistic reasoning illustrates:

LURIA: Cotton can't grow where it's cold, and it's cold in England. Does cotton grow there or not?

KHAMRAK (an illiterate miller from a remote village): If it's cold it won't grow, while if it's hot it will. From your words, I would have to say that cotton shouldn't grow there. But I would have to know what spring is like there, what kinds of nights they have.

Khamrak, to be sure, is distrustful of reasoning from *a priori* premises. But may it not reflect a deeper adaptation to a mode of life where skill and experience count more than in a technical society, such that knowing *that* is subordinated to knowing *how*?

The work of Cole and Scribner, of Horton, and of Labov, all indicate that cultural factors produce a different deployment of universal, basic cognitive and intellectual processes of different peoples, that these deployments do not on close inspection turn out to be any less 'rational' when applied to one set of circumstances than any other. Personally, I would rather trust Khamrak with local agricultural decisions than most of my Oxford undergraduates who could solve the cotton syllogism in a trice. Perhaps the fault lies with the use of a developmental model to account for differences produced by differingly technical cultures.

Be that as it may, the book is rich in data and observation on the nature and transformation of the peasant mentality into the more familiar 'rational' reckoning of those who went on to run the tractor pools and marketing arrangement of the *kolkhoz* that transformed Soviet agriculture and life in the country. Luria brings a rare genius to the task, managing, as he has in his past books, to find the germ of generality in the everyday particulars to which he brings his observational skills.

Jerome Bruner

Biomolecular mixture

Intermolecular Interactions and Biomolecular Organisation. By A. J. Hopfinger. Pp. xviii + 395. (Wiley Inter-Science: New York and London, 1977.) $33; £19.50.

NEW results in science are published and then reviewed in journals specialising in broad or narrow topics of current interest. Books should be different in that they represent a new synthesis of fact and theory collected and distilled into a coherent and useful entity. Unfortunately, we are facing a deluge of books which offer very little that has not earlier been given in closely related form. The volume under review, although attractively titled, is a compilation of disjointed topics with no visible thread leading from one to the other. One cannot hope to learn from it about the theory of solutions of macromolecules, or conformational analysis by nuclear magnetic resonance, or quantum mechanical calculations, nor can one form a critical opinion about how these connect to the problem of drug design, for instance, to which a whole chapter is devoted. I found particularly revealing the admission of the author that large portions of his book are indeed taken (p145 or p252, for instance) "from the excellent review" of other authors!

After trying to examine the extensive subject matter somewhat more closely, I am reminded of a story told by the late author, Maurice Samuel, in his quest to evaluate the widely ranging work of a famous contemporary historian. All fellow historians approached indeed acquiesced that his study of history seemed highly significant; however, as far as their own speciality was concerned, they voiced grave reservations. Trying to evaluate not only the breadth of the present work, but rather the depth to which individual topics are treated, particularly those with which I am familiar, I ran into similar difficulties. To mention a few examples only, our own work on hydration of DNA is incorrectly quoted (p160), lumped together with other quotes in purely irrelevant fashion. Concerning our work quoted in the footnote of Table 8-1, viscometry of DNA cannot be used directly to compute the number of intercalated dye molecules. On p265, part of the enormous Table 12—1, the author reprints an incorrect finding first made in 1958, and then often repeated, that glutamic dehydrogenase is a zinc enzyme with a molecular weight of 1,000,000 containing two to six Zn molecules. For many years now it has been known that glutamic dehydrogenase has a molecular weight of six times 56,000 and does not contain Zn. The discussion on nucleohistone aggregation and chromatin structure in chapter 13 is largely outdated and would be unintelligible to the uninitiated. Space does not permit me to go into other examples, which abound.

The proof-reading is sloppy beyond the border of insult. Having myself recently published a book, I know how difficult it is to win the battle with publisher and printer. Yet one must try. The author is responsible that the same name is spelt Fahien, Fehiem, Fahiem on one page(152), Subivana and Subirama (the correct name is Subirana) on p204, and Schleich, Scheich and Schiech in chapter 12. There are many more such examples. A carefully proof-read name index would have been helpful in a work which draws on so many varied sources.

Henryk Eisenberg is Professor of Biophysics and Head of the Polymer Department at the Weizmann Institute of Science, Rehovot, Israel.

Science policy yearbook

Science and Government Report International Almanac, 1977. Edited by Daniel S. Greenberg. Pp. 305. (Science and Government Report: Washington DC, 1977.) $54 before 1 September; afterwards $75.

THIS first volume in what is intended as an annual series introduces the idea of a 'science policy yearbook'. Part I consists of 20 chapters which survey, nation-by-nation, major recent developments in science and technology policy. Most authors are experienced science journalists (not a few of whose names will be well known to *Nature* readers), and the chapters are concise, informative and wholly unpolemical. Each covers more or less similar ground: changing priorities; research and development expenditure; changes in government research organisation and science policy advisory machinery; and issues which in the country concerned have been publicly contentious.

I personally enjoyed this part of the book and can recommend it to anyone who wants to keep broadly in touch with what is happening on the interface between science and government in a wide range of countries. Though more readable than the products of international organisations active in this field, it lacks the systematic quantitative data which often makes their reports a useful basis for further analysis.

Part 2 of the book, an international directory of major scientific organisations and science policy personnel, though commendably up to date, is curiously haphazard in its coverage. Thus, although we find listed British Departmental Chief Scientists and Britain's Scientific Counsellors overseas, the only organisations whose addresses and functions are given are the Central Policy Review Staff in the Cabinet Office, the SRC, MRC and Department of Energy.

Part 3 gives excerpts from eight recent (mostly American) science policy documents, including President Carter's campaign speeches and the NIH guidelines on recombinant DNA experiments.

On balance, the yearbook idea is an interesting one, and libraries might wish to acquire this first effort notably for the contents of Part 1.

Stuart S. Blume

Stuart S. Blume has worked on science policy issues at the OECD, the Science Policy Research Unit at the University of Sussex, UK, and in various governmental posts.

Early development and gene activity

Gene Activity in Early Development. Second edition. By Eric H. Davidson. Pp. xvi+452. (Academic: London and New York, 1977.) £11.30.

THIS is an enlarged and completely rewritten edition of Dr Davidson's successful 1968 book of the same title. It is the only comprehensive review, at the molecular level, of early animal development, and provides a scholarly and unbiased account of the field as it now stands. It will be invaluable to research scientists and advanced students interested in this field.

The book consists of eight chapters, covering the following topics; the constancy of the genome; the initiation of genomic control and of cell differences; the changing populations of proteins and RNAs in embryos; cytoplasmic determinants, and oogenesis. Each chapter is preceded by a summary of the principal facts. Within most chapters, results are presented according to taxonomic groups. This is a wise decision, because there are remarkable differences in the morphological and molecular characteristics of development of different animals, a situation which has made it impossible so far to identify any universal mechanism of development applicable to all animals. One chapter provides a very helpful explanation of renaturation and molecular hybridisation experiments, such as have been used in much of the author's own work. One of the particularly good characteristics of the first edition which has been retained is the survey of classical embryological literature. This is especially valuable since most of those engaged in the molecular analysis of early development have no familiarity with, or convenient access to, early literature of this type. A detailed and very representative bibliography of original papers and their titles, up to the middle of 1976, is provided.

The general theme which lies behind most of the work reviewed in this book is the importance of gene activity in development. The author's view is that during oogenesis (egg formation) gene products are accumulated. Soon after fertilisation, they are moved to different positions in the egg, and as a result, they (or other molecules formed by their activity) cause activation of different genes in different cells. These activated genes start to make their own products during gastrulation and at later stages. This represents a fairly conventional view of early development, having been favoured by many writers since the end of the last century. Certainly the detailed evidence summarised in this book does a lot to bolster one's confidence in this hypothesis.

It is currently fashionable to devote much attention to cell surface molecules, and those who fall into this class may feel that this aspect of the molecular repertoire of cells is lightly represented. There is no evidence at present, however, that any of these molecules are causally connected with development. An area of relevant information which is not covered in this book concerns the molecular differences between highly specialised adult cells. It is possible that a detailed molecular description of differences between adult cells may lead more directly to an understanding of early developmental processes than a description of molecular changes which take place in embryos themselves.

As is evident from reading this book, two factors restrict progress in this field. One is the lack of a detailed description of the activity of single known genes; the other is the absence of a way of distinguishing genes and gene products which are important in development from those which merely accompany this process in a non-causal way. Procedures are becoming available by which these kinds of information can be obtained; but for many years to come, this book is likely to be a standard reference work for all those interested in early development and gene activity. **J. B. Gurdon**

J. B. Gurdon is a research worker at the MRC Molecular Biology Laboratory, Cambridge, UK.

Tilting at windmills

Ecological Sanity. By George Claus and Karen Bolander. Pp. xv+592. (David McKay: New York, 1977.) $16.95.

IT is difficult to understand why the David McKay Company of New York have bothered to publish this book in 1977. They very honestly admit in a note at the front that the research (*sic*) on which it was based was completed in 1972, and that it was delayed by "production difficulties beyond our control or that of the authors". The authors' Preface has a dateline "Vienna 1972". The publishers state that they are "confident that the continued significance of this book will be apparent to the reader". Unfortunately this does not apply to this reviewer.

Ecological Sanity sets out to give a critical examination of the statements made by the so-called "Ecological Lobby", particularly in the United States. The lobby is accused of putting forward statements which cannot be supported by sound research, and for making premature Doomsday announcements. This is all set out at great length, for the book is not far short of 300,000 words. Had it appeared in 1972 it might have been of some interest, although even by then many other authors had already produced more effective criticisms of the errors put forward by the more extreme environmentalists who had assumed the title of "the ecologists". It is true that some of these extremists are still unrepentant, although many have either recanted or disappeared from the scene. Claus and Bolander are, for the most part, tilting at windmills, for the situation is very different from that which obtained five years ago. A far greater number of people, particularly those in authority, are able to view the scene more rationally. Thus, the World Health Organisation still recommends DDT for malaria control in appropriate situations, although the dangers of misuse are fully recognised. The more absurd statements of the lobby have been recognised as such; their other efforts to keep the rest of us on our toes, is probably a good thing.

There has, of course, been controversy about pesticides, particularly the organochlorine insecticides. The 275 pages of small print (almost half the book) on this subject is particularly unsatisfactory. It is true that, in the late 1960s and early 1970s, some environmentalists extrapolated unjustifiably from the results of research. There has, however, been a great deal more work done in the past five years. Some of this disproves conclusions based on extrapolations, some supports conclusions hitherto unproven. This omission of what is now the major part of the relevant research means that the book is of interest only to the historian of the bye-ways of science.

Yet there is still a need for us to be reminded of the need for ecological sanity, even if this book does little to achieve this objective. Environmental dangers still exist, and it is as bad to exaggerate their importance as to refuse to recognise their existence. Resources will always be limited, and environmental protection will always be subject to compromise. This is unfortunately not as glamorous as extremism from the "right" or from the "left". **Kenneth Mellanby**

Kenneth Mellanby is Editor of Environmental Pollution, *and was formerly Director of Monks Wood Experimental Station, Huntingdon, UK.*

obituary

Sir Graham Sutton

Sir Graham Sutton, former Director-General of the Meteorological Office, who died on 26 May 1977 at the age of 74, achieved eminence early in his career by fundamental contributions to the theory of atmospheric turbulence and diffusion.

His work in this field began in the late 1920s, when atmospheric boundary-layer theory was at a primitive stage. It had, however, become evident, from early observations of diffusion and from pioneering theoretical studies by G. I. Taylor and L. F. Richardson, that the diffusion of a plume of smoke could not be explained on the basis of a constant eddy diffusivity analogous to, but very much larger than, the molecular diffusivity of kinetic theory. The starting point of Sutton's theory of turbulent transfer was the combination of Taylor's famous theorem, for the kinetics of passive particles carried in a turbulent fluid, with the classical Prandtl mixing-length theory. This led to an explicit height-dependent form of the eddy diffusivity. It also led to the result that the spread of a plume of gas or fine particles issuing from a point in a wind was proportional to distance raised to a power between $\frac{1}{2}$ and 1, the precise magnitude of this exponent and of the proportionality constant being determined by the form of the increase of wind with height above ground.

The consequences of this work have been wide-ranging and long-lasting. It provided the basis for the first formulae representing the effect of meteorological conditions on the concentration-field downwind of a source of gas or particles, and Sutton's point-source formulae, at first in restricted use in chemical warfare studies, became widely known immediately after the 1939–45 war in the context of industrial air pollution. It also was a stimulus for continuing and far-reaching boundary-layer studies, notably of the wind profile, the aerodynamic drag of the earth's surface and the factors determining evaporation from water surfaces and transpiration from vegetation.

Oliver Graham Sutton was born in Cwmcarn, Monmouthshire, in 1903. He took his degrees in mathematics at Aberystwyth and Oxford and his first appointment was to a lectureship at Aberystwyth. Two years later, in 1928, he was persuaded by the late Sir David Brunt to join the Meteorological Office and shortly afterwards he was seconded to the War Office establishment at Porton, where the aforementioned work was carried out.

Clair-Continental

In 1942, with his potential for scientific administration already strongly evident, he was required to leave his meteorological team for wider wartime responsibilities as Superintendent of Research at Porton, and he was drawn into further fields of administration in posts as Superintendent of the Tank Armament Research Station (1943–45) and Chief Superintendent of the Radio Research and Development Establishment (1945–47).

In 1947 he returned to individual scientific work in the position of Bashforth Professor of Mathematical Physics at the Royal Military College of Science, Shrivenham, though here also wider responsibilities were to be placed on him, as Scientific Adviser to the Army Council (1951) and Dean of the Royal Military College (1952–53). His individual scientific achievements were recognised in his election as a Fellow of the Royal Society in 1949.

During this phase of his career he was able to turn to more general writing on the fundamental science of boundary-layer meteorology, an ambition on which he had made a start while at Porton. His first published effort was *Atmospheric Turbulence* in the Methuen Monograph series (1949) and this was followed by his well-known major work *Micrometeorology* (1953), in which he covered the most important topics in the physics of the surface air layers. Although much had already been written on the qualitative aspects of those topics, *Micrometeorology* was the first connected account of the relevant principles and crucial observations in a full mathematical–physical setting. His capacity for exact mathematical analysis and lucid exposition of complex physical interpretations came out here to the full, and he was to make good use of the latter gift over more than two decades of writing for less specialised readers, as for example in his *Science of Flight* (1950) and *The Weather* (1974).

In 1953 Dr Sutton accepted an invitation to become Director-General of the Meteorological Office, and for the next twelve years devoted his mature powers of leadership, scientific judgement and administrative skill to the formidable task of guiding its developing activities. His period of office saw the emergence of a fully-developed research division with the scope and reputation of a leading institute of meteorology. Technical resources were greatly expanded and included the installation of high-speed computing facilities. The services which meteorological science could usefully offer were extended far beyond those originally designed for weather forecasting and aviation. At the same time the hitherto scattered main branches of the Office were brought together in the present unified headquarters at Bracknell.

Sir Graham (he was knighted in 1955) planned to retire from professional activities in 1965, but he was then persuaded to be first chairman of the Natural Environment Research Council. Here again his outstanding abilities as an administrator and his qualities of leadership were turned to an urgent and important task, that of ensuring the rapid and successful development of the new organisation for promoting the various sciences of the natural environment.

The many recognitions and awards received by Sir Graham included the Symons Memorial Gold Medal of the Royal Meteorological Society (1959), the International Meteorological Organization Prize (1968) and the Frank A. Chambers Award of the United States Air Pollution Control Association (1968). There were also countless demands on his time for work on committees and in other organisations, and to many spells of service as chairman he invariably brought a balanced judgement, a diplomatic touch and a quiet sense of humour. While Director-General of the Meteorological Office he took a prominent part in the activities of the World Meteorological Organisation, especially as a member of its Executive Committee. He was President of the Royal Meteorological Society 1953–55. He also found time for the duties of a Justice of the Peace and for those of a member of the Council of the University College of Wales, Aberystwyth, of which he was Vice-President in his last few years.

F. Pasquill

A. D. Walsh

PROFESSOR A. DONALD WALSH FRS died in Dundee, after a long illness, on 23 April 1977 in his sixty-first year. He was educated at Loughborough Grammar School and Corpus Christi College, Cambridge, where he was a Mawson Scholar. In 1938 he started research in vacuum ultra-violet spectroscopy under the direction of Professor W. C. Price and continued as an ICI Research Fellow until 1949, when he accepted a lectureship at Leeds University. In 1953 he was promoted to a Readership, and two years later was invited to take the Baxter Chair of Chemistry at Queen's College, Dundee, which was then part of the University of St. Andrews. In 1967, when Queen's College became the University of Dundee, Professor Walsh was appointed Dean of the Science Faculty. He was elected to the Royal Society of Edinburgh in 1959 and to the Royal Society in 1964.

Donald Walsh will always be remembered for his enthusiasm. Whether he was lecturing to a first-year class, discussing his latest research, or watching the flight of a bird while driving erratically along a country road, he radiated a fascinating and infectious enthusiasm for his subject.

It was this enthusiasm which marked his rise to the heights of his profession. The investigation of the electronic structure of small molecules and the nature of valence and chemical bonding were, for him, an absorbing study throughout his career. The topic suited his enquiring mind ideally, for he loved to put his ideas to the test and spent very many happy days fitting together his theories and his experimental spectra.

During the war, when it became necessary for research to have more practical application, Donald Walsh became involved in problems of gaseous combustion, such as the suppression of the exhaust flames which revealed the presence of our aeroplanes in the sky at night. After the war, he became more interested in the mechanism of gaseous combustion reactions, and in particular with the mechanism of anti-knocks in petrol engines. In this he was associated with Riccardo Ltd and later with Octel Ltd who still employ a number of his former students. Those privileged to hear him present his research papers in the 1950s and 1960s will clearly recall the rival theories on anti-knock action put forward by Professors R. G. W. Norrish and A. D. Walsh, the debates being enlivened by the completely different personalities of these two eminent scientists. Donald Walsh was fond of simple experiments to demonstrate his ideas. One remembers the hydrogen peroxide which usually hit the ceiling in a demonstration that peroxides are rapidly decomposed by particulate lead oxide (an important part of his theory of the anti-knock action of lead alkyls.)

In Dundee his gentlemanly charm and hospitality quickly gained for him the loyalty of a department which rapidly grew under his direction and enthusiasm. His research students enjoyed many happy Saturday afternoons helping him construct his large garden, and they appreciated the generous quantities of Elin Walsh's magnificent teas which contrasted so markedly with student fare.

When Dundee gained independent status as a university in 1967, Donald Walsh was the obvious choice for Dean of the Faculty of Science—a Faculty which might have disappeared earlier but for his efforts. Extra duties did not deter him, and he habitually arrived in the Department at 6 a.m. after an overnight journey from London—he was still there at 7 p.m.

He bore his long fight with Parkinson's disease with typical fortitude as he was gradually forced to retire from chemistry and from the department to which he had devoted so much of his time and energy.

D. E. Hoare
P. A. Warsop

R. D. Brauer

RICHARD DAGOBERT BRAUER, who was one of the leading pure mathematicians of this century, died on 17 April 1977 at Belmont, Massachusetts. Born in Berlin in 1901, he studied at the university there under the distinguished algebraist Issai Schur. He taught at Königsberg until the political oppression in Germany forced him to leave in 1933. He held temporary posts at the University of Kentucky and the Institute for Advanced Study in Princeton. In 1935 he went to the University of Toronto, where he stayed until 1948; he then returned to the United States, and held chairs at the Universities of Michigan (1948–1952) and Harvard (1952–1971).

Brauer's work on the representation theory of groups has been a major influence in the development of algebra during the past half-century. Some of his earlier papers were concerned with the representations of semisimple continuous groups—Hermann Weyl's fundamental work on this subject appeared at about the time (1925–1926) when Brauer was presenting his doctoral thesis. Brauer's methods were more algebraic, and in some ways simpler than Weyl's. In fact Brauer worked as assistant to Weyl in Princeton in the year 1934–1935, and they wrote there a joint paper on spinors, which is the classical exposition of the mathematical background to Dirac's theory of the spinning electron.

From 1935 onwards, Brauer was increasingly concerned with the representation theory of finite groups. He developed a beautiful and deep theory of modular characters, which gave a completely new insight into the study of group characters. Group characters had been introduced in 1896 by Frobenius, and had already given, in the first decade of this century, some remarkable results on the structure of finite groups. It was Brauer who, thirty years later, resumed this work, and by the end of the 1950s had laid the foundation of a method for attacking the very difficult problem of the classification of finite simple groups. His pioneering work was one of the starting points of a great advance in this problem. Brauer's active involvement in this research continued right up to the end of his life.

During his long career Richard Brauer received many academic honours and held some of the highest positions in his profession. But he retained a very gentle and unassuming manner, and a concern for the problems and interests of other mathematicians. His modesty about his own great achievements was proverbial—a mathematical conversation with him would usually become a conversation about the other person's work. A first impression of unworldliness was deceptive; he used his time very efficiently, and achieved a great deal in an unhurried manner. He became a kind of elder statesman among American algebraists, and his advice was sought and valued for its wisdom and humanity.

He is survived by his wife Ilse (née Karger) whom he married in 1925; also by his brother Alfred, and his two sons George and Fred, who are all mathematicians.

J. A. Green

what's new–chromatographs

In addition to the regular Newly on the Market section in *Nature*, special features on a particular type of laboratory equipment or instrumentation will be published in this and forthcoming issues. The issue of 20 October will be on Spectrometers and ancillary equipment.

The purpose of a special feature is not to give listings of every item in the range of the manufacturers mentioned but to take a variety of equipment of interest in that feature area and give an idea of what kinds of instruments are available and from whom. There is a Reader Enquiry Coupon facing the inside back cover.

EDT Research now have a demonstration Jobin-Yvon Chromatospac preparative liquid chromatograph in the UK. This instrument has a loading capacity of 100 g of sample per injection and can provide high performance (typically 7,000 theoretical plates per m with TLC grade silica). Many different types of stationary phase have been used successfully including alumina and silanised silica for reverse phase. A unique pressure packing system for the stationary phase provides excellent reproducibility. The instrument also has the capacity to operate in the partial elution mode, as the stationary phase can be completly removed from the cylinder.

Circle No. 37 on Reader Enquiry Coupon

Phase Separations Ltd present HPLC adsorbents. Spherisorb is a range of highly efficient, totally porous, particles for HPLC and the range of materials is based upon 5 μm, 10 μm and 20 μm particles of alumina and silica with a variety of chemically bonded phases for reverse phase chromatography. The Model 1203 from Laboratory Data Control is a very sensitive ultraviolet detector designed specifically for use in HPLC and has selectable ranges from 0.002 to 2.048 aufs. The new detector has a noise level (typical short term) of 2×10^{-5} au (P to P). A new range of glass capillary columns is now available. Both wall coated open tubular and support coated open tubular are available with a wide variety of stationary phases.

Circle No. 38 on Reader Enquiry Coupon

Knauer present a range of equipment: a differential refractometer for analytical and preparative use; a high temperature refractometer up to 160 °C; ultraviolet filter photometer (254 nm); a spectral photometer (200–600 nm); uv/ri dual detector; a double filter photometer (254–600 nm); a fluorescence detector; combination ultraviolet and fluorescence detector and conductivity detector. Knauer columns have specific advantages, namely, the inside diameter of the stainless steel column is especially honed to provide a highly polished surface and precise concentricity; symmetrical construction makes 'backflush' possible; the column ends have integral machined threaded terminations for safety. A replaceable seal is used instead of a ferrule, so columns can always be refilled. Stainless steel sieves and a fibreglass filter are used to retain all particules larger than 2 μm. Knauer HPLC columns are modular in construction. The optimum separations obtained with analytical columns can also be expected with the preparative columns. The preparative columns (16 mm i.d., length 25 cm and 50 cm) may be packed with the same finely granulated packing materials as the analytical columns (4, 6 mm i.d.). The use of a 'stream distributor' in the column, produced a uniform spread of the sample onto the surface of the column and low dead-volume elute flow.

Circle No. 39 on Reader Enquiry Coupon

Knauer Dualdetektor

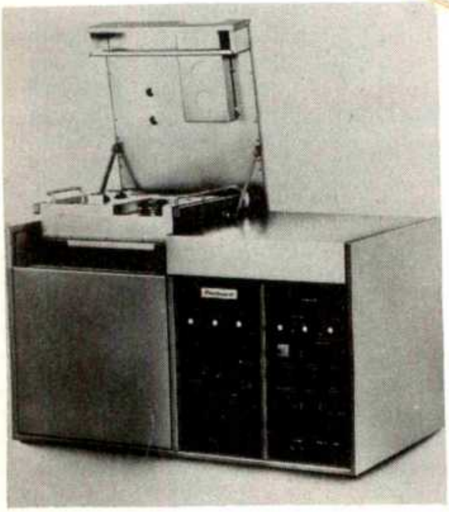
Rofin announce the Chromatix KMX-6, a revolutionary low angle light scattering photometer which utilises the spatial characteristics of a small, single transverse mode laser. The patented design allows measurement of scattering at forward angles of less than 2° from the incident beam, and permits weight-average molecular weights to be obtained on an absolute basis in minutes, without recourse to an arbitrary standard. At such low angles, weight-average molecular weights may be calculated from scattering measurements at a single concentration and angle, if the solute second virial coefficient is known. When the second virial coefficient has not been determined, the data need only be extrapolated to zero concentration by making measurements at two or more concentrations: no angular extrapolation is required. Rapid instrumental response makes high speed kinetic measurements possible, and when combined with a computer and gel permeation chromatograph, molecular weight distributions can be determined. The high sensitivity and many unique design features of the KMX-6 permit it to be applied to a variety of applications in many different scientific fields, such as molecular weight determinations, molecular weight distribution (with GPC), macromolecular kinetics (enzyme and antibody-antigen reactions, dimerisation, etc.), single particle fluorescence and nephelometry, molecular interactions (virial coefficients), molecular conformation (radius of gyration), molecular anisotropy (depolarisation), Rayleigh spectroscopy (diffusion coefficients), Brillouin spectroscopy (acoustic modulation), and refractometry.

Circle No. 40 on Reader Enquiry Coupon

Whatman supply a vast range of chromatography columns and packings and modern liquid chromatography of nucleic acid constituents and other other naturally occurring compounds. Whatman offers the widest choice of prepacked columns and loose media commercially available. Silica gels, aluminas, polyamide, bonded phases for reversed-phase and normal phase chromatography are available in both prepacked, pretested columns and as loose media. Many of these have direct application in HPLC for separation of different classes of biologically significant compounds, e.g., steroids may be separated on Partisil. Various types of Partisil appropriate for different types of chromatology are available e.g., Partisil-10 PAC, for normal phase partition, HP2C, a complement to Partisil-10 ODS, a microparticle non-partition bonded phase for

reverse-phase HPLC and so on. Both pellicular and microparticulate media are available. The microparticle-support bonded ion exchangers are increasingly important ion exchange media because of higher efficiencies, greater loading capacity and other characteristics. Nevertheless the pellicular forms will continue to have an important role since packing of columns with microparticulates in the laboratory requires experience and apparatus not commonly available; in contrast ion exchangers in pellicular form are easily dry packed. Further, microparticle packings perform optimally when the chromatographer is experienced enough to be able to fully utilise their inherent superiority. In general, then, pelliculars are used until the techniques of modern liquid chromatography are mastered. One benefit of pellicular ion exchangers is that they are relatively unaffected by sample contamination. Should the pellicular column become inoperable due to impurities in the sample, the contaminated portion of the column bed may be removed and replaced with new media.
Circle No. 41 on Reader Enquiry Coupon

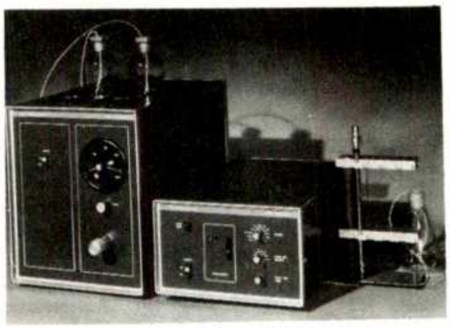
Packard introduce the 428 Series gas chromatographs which combines requirements for accuracy and reproducibility with unique analytical and instrumental flexibility. The analytical flexibility is provided through the column oven cover which contains dual injection ports, dual detectors and columns. This analytical module is a plug-in unit, thus providing the possibility to change the complete GC analysis system in minutes. Instrumental flexibility is achieved by the use of plug-in electronic modules and plug-in flow control units. Any dual detector configuration is possible, eg, dual FID, dual ECD, ECD/FID, TCD/FID etc.
Circle No. 42 on Reader Enquiry Coupon



Packard 42F Chromatograph

Pye Unicam present a wide range of general and high performance chromatography equipment. The analyst involved in repetitive routine gas chromatography analyses requires a reliable low cost, compact workhorse to achieve a steady throughput of results. The GCD chromatographs are to meet this demand.

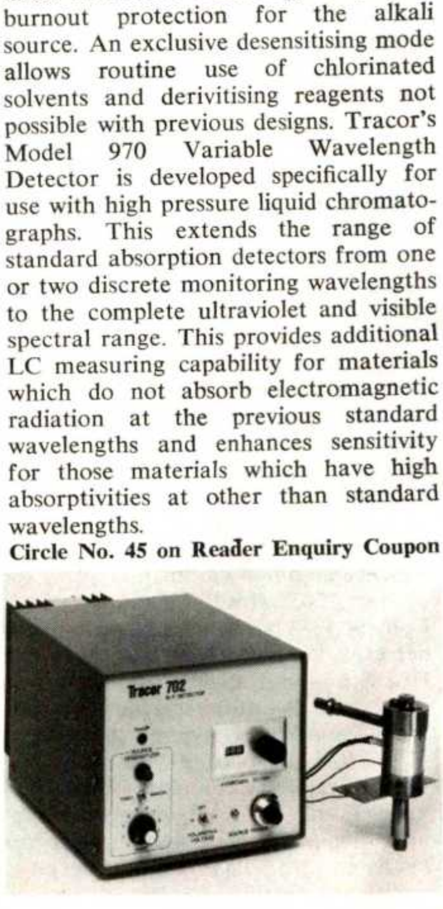
Typical applications for the GCD are to be found in laboratories engaged in multiple analyses such as quality control in the oil and gas industry, air pollution measurement and routine screening for drugs and hormones in clinical chemistry. These new flame ionisation chromatographs incorporate dual heated injection ports and dual heated flame ionisation detectors for dual column operation. Temperature control of the column oven may be chosen from isothermal or temperature programming; with conversion from isothermal to temperature programme being able to be carried out at any time. The basic chromatograph's also include a wide range ionisation amplifier, separate injector and detector oven temperature setting controls, and readout of temperature from the injectors, column oven and detector oven. The most useful accessory is the Autojector S8 which completely automates measurement of sample volume and injection of liquid samples. It is a self contained accessory which utilises punched tape to control the sequence of events that occur during the sample injection cycle. Standard tapes give facilities for six washes of the syringe before injection solvent washing of the syringe, control of integrators and identification of each analysis on the chromatogram. The sample turntable has a capacity for up to 100 samples which allows the instrument to operate unattended over long periods of time. A built-in interval timer determines the period between analyses, and may be set between the limits 0–120 min. The new Series 204 has modular construction providing a complete range of analytical gas chromatographs, starting from a simple instrument which can be subsequently extended to a fully automatic system. The basic oven assembly is suitable for single or dual column operation and includes injector, detector and column ovens all with temperature readout. A choice of five detectors is available, any two of which may be operated simultaneously. The Autojector 8 can also be integrated. The new Series 604 process chromatograph system is also geared to the less complex applications and extensions up to six streams and six components can be handled with ease and economy, due to modular extension for sample handling, analysis and programming.
Circle No. 43 on Reader Enquiry Coupon



Pye Unicam LC3

The Dickinson Instrument Company announces a Linear Gradient Maker for column chromatography and gel electrophoresis. The linear concentration gradient maker has been designed for use in column chromatography and gel electrophoresis. Mixing is accomplished by placing the gradient maker on a magnetic stirrer. Out flow is by gravity or peristaltic pump. The apparatus has a unique, leak proof valve which provides easy access, positive on-off control, with no cross hole to line up. 1,200,600 or 300 ml sizes.
Circle No. 44 on Reader Enquiry Coupon

Tracor introduces a new detector, the third generation nitrogen-phosphorous GC detector. Model 702 which combines unique mechanical design with latest electronic technology to provide burnout protection for the alkali source. An exclusive desensitising mode allows routine use of chlorinated solvents and derivitising reagents not possible with previous designs. Tracor's Model 970 Variable Wavelength Detector is developed specifically for use with high pressure liquid chromatographs. This extends the range of standard absorption detectors from one or two discrete monitoring wavelengths to the complete ultraviolet and visible spectral range. This provides additional LC measuring capability for materials which do not absorb electromagnetic radiation at the previous standard wavelengths and enhances sensitivity for those materials which have high absorptivities at other than standard wavelengths.
Circle No. 45 on Reader Enquiry Coupon



Tracor 702

Hewlett-Packard offer a new compact high performance liquid chromatograph, the HP 1081A which performs basic LC functions with an accuracy and repeatability similar to that of other members of the HP 1080 family of liquid chromatographs, but at a fraction of the price of the top-of-the-line HP liquid chromatograph. The heart of the instrument's virtually pulseless flow system is a single-head diaphragm pump whose strokes can be adjusted by a pushbutton-controlled stepping motor to set the solvent flow. The pump design assures excellent flow stability. The selected pump-stroke position and the resulting column pressure (bar) are shown on the unit's three-digit numeric display. A valve loop injector, allowing sample introduction at full column pressure without interrupting flow, comes standard with a 20-μl loop, but 10-, 50-, and 100-μl loops are also available. Other features of the flow system include a 2-l solvent reservoir with purge-gas connection and a column compartment that, although not heated, provides a protected column environment. The 1081A has a single wavelength UV detector with high signal-to-noise ratio that operates at 254 nm. The instrument, with its analog-signal output, can be linked directly to conventional integrators and strip-chart recorders. Interfacing the 1081A to a computer-based laboratory automation system is possible when an A to D converter is added. The HP 1080 Series LC family concept includes downward compatability. Analytical methods within the capability of the new 1081A can be developed on the larger, processor-based HP 1084A, the most powerful LC of the HP product line. The new methods, then, can be transferred for routine work to the smaller HP 1081A with comparable precision. The HP 5985A, with dual chemical/electron ionisation source, provides greater flexibility in measurement and data handling with such advanced features as automatic tuning, an efficient hyperbolic quadrupole mass filter, a microprocessor-controlled GC, a powerful HP 21MX E Series computer and all-digital electronics. Mass range is 10-1,000 amu and sensitiviy is to picogram levels, essential for the analysis of pesticide pollution, drug and biological samples. The instruments new inlet system is specifically designed for both packed and capillary column operation in either CI or EI mode. Sample injections may be split in a variable ratio between the GC and MS detectors to provide simultaneous quantitative GC analysis and positive identification of mass spectra in the same run. The gas chromatograph used in the system is a second-generation, microprocessor-controlled HP 5840A. This dual-column GC can be equipped with multiple detectors including dual-flame ionisation, dual-thermal-conductivity, flame-photo-metric, nitrogen-phosphorus and electron-capture detectors.

Coulter Electronics Ltd introduce the Model 725 automatic injector for use with high performance liquid chromatography systems. In use it allows the automatic, unattended injection of up to 64 consecutive samples with negligible carryover between samples. The unit is microprocessor operated and it controls the number of sample injections (up to 3 per vial), injection time, rinse between sample (if desired) and automatic shut-down after completion of last sample or detection of an instrument malfunction. It uses inexpensive disposable glass vials with a unique feature. The vials caps act as a piston to discharge sample with a positive flow. Only 700 μl of sample is required and the injection valves will operate at pressures up to 6,000 p.s.i. and a 10 μl sample loop is fitted as a standard. The unit can be used with any HPLC system and it can be controlled by a computer or integrator.

Schoeffel introduce a new and improved, extremely-sensitive continuously variable wavelength flourescence detector for liquid chromatography. While using standard tested fluorometric technique, this new instrument offers advanced design features necessary for obtaining sensitivities required for measurements of minute fractions achieved by the superior separation capability of HPLC. Extreme care was taken to prevent fraction mixing and dead volume influence, and a unique to be efficiently collected from rather dead volume influence, and a unique 2π streadian cuvette design (5μl) resulted. This development enables light to be efficiently collected from rather weak fluorescing signals emitted from minute sample quantities (typical sample size in picogram range). The FS 970 uses a broad band deuterium (or tungsten) lamp with a high throughput monochromator to enable the user to work at the compound's absorption maximum and to assure that a wide and variable spectral range is usable. This offers the investigator greater versatility since compounds can often be excited at several wavelength. The fluorescence emission measurement system consists of a superior end-on, state of the art photomultiplier tube and a solid state photometer to offer maximum sensitivity.

Schoeffel SDC300/3000

ESI Nuclear introduce a new universal radioactivity detector for gas chromatography. Light and compact, the advanced design of the new system has resulted in easy, clear controls highly suitable for the less experienced laboratory personnel. It is of great use to those involved in drug and pesticide metabolism, research or similar fields. ^{14}C labelled effluent from a gas chromatograph is passed through a furnace containing copper oxide. The ^{14}C is oxidised, passed over a drying agent, and finally counted in a gas-flow proportional counter to determine the radioactive content. Tritium compounds may also be analysed in this way by the use of an additional reduction stage containing iron filings. The new universal 505 system has a flexible heated stainless steel tube which is temperature controlled to prevent condensation of the sample in the tube connecting the gas chromatograph to the radioactivity detector.

Lignes Télégraphiques et Téléphoniques present microprocessor computing-integrators ICAP 10 and ICAP 5 for gas and liquid chromatography and amino-acid analysers. The two main functions are chromatogram processing and concentrations computing. They permit flexible measurement of the area of sophisticated peaks from modern chromatographs and measure, compute and visualise absolute or relative retention time. Also the micro-computing part of the systems allows the concentration calculation after introduction of response factors of each component either simple standardisation or according to an internal or external standard.

Laboratory Impex Ltd offers specialist equipment for the monitoring of radioisotpe tracers used in both liquid and gas chromotagraphs. The company brings together the ICN Instruments Coruflow high performance liquid scintillation detector head and its locally manufactured counting electronics and accessories to provide extremely sensitive systems for elluents containing ^{14}C, Tritium and other beta radiation emittors. The use of continuous flow monitors for radio tracers with HPLC has been made possible by improved flow cell design and detector performance and brings several additional benefits over the classical method of fraction collection and separate sample counting. The most important are that (1) sample material is almost always 100% recoverable (cf normal scintillation counting); (2) results are obtained immediately enabling experiments to proceed faster; (3) frees expensive liquid scintillation sample changers for other work.

Erba Science (UK) Ltd announce a series of gas chromatographs, particularly suited for capillary column applications. The current range includes: Model 2151, a well established, reliable instrument which comes complete with a FID, electrometer, oven temperature controls, carrier and auxillary gas controls, temperature programmer, Grob splitless injector and 20 m Jaeggi column Model 2351, the dual column version of Model 2151 which, in addition to the units and service outlined above, comes complete with constant flow controllers for each of the carrier gas lines, plus independent pressure regulators and pressure gauges for each of the supplies to the two detectors. Model 2900 is the newly introduced capillary dedicated gas chromatograph which may be used with split or splitless sample injectors, single or dual columns and a range of detectors. The standard specification incorporates a fast response electrometer, a large volume column oven with drop down door, digital temperature settings with readout on five points, right and left hand connections for a mass spectrometer and a heat exchanger for sub ambient operation. One of the main features of the Carlo Erba range of gas chromatographs related to capillary column work, is the lack of dead volume. This is due to an on column injection system and a unique column detector coupling which allows the column outlet to be positioned at the detector jet.

Techmation present, for the random access analysis of refinery gas the automatic Series-S AGC which provides multiple access analysis of the hydrocarbons and inerts of interest in various types of refinery gases. The choice of two sample valve entry points for introducing samples enables determination of components of particular or immediate interest 'out of turn' from the order dictated by a single sample sequential analysis. Four columns are used in conjunction with two multifunction gas sampling valves and a function gas sampling valves and a column switching valve. Also included for sensitive, linear measurement of hydrogen while retaining sensitivity for other components is Carle's Hydrogen Transfer System (HTS). All valve switching is, of course, automatic.

Erba Science IIIH

Pharmacia Fine Chemicals present a new range of high performance columns and accessories for liquid chromatography in the life sciences. All components are solvent resistant and operate at pressures up to $10\ \mathrm{kg\ cm^{-2}}$ (140 lbs per square inch). They are autoclavable and fully compatible with biological substances. The system includes colmuns SR 10/50 J and SR 10/50, columns with i.d. 10 mm and length 500 mm, with or without thermostat jacket. The columns are supplied with flow adaptors as standard. The complete range of accessories for column packing, recycling chromatography, upward flow elution and operation of columns in series consists of: column extension SRE-10, stopcock valve SRV-1; single-channel, four port valve SRV-3; two-channel, four port valve SRV-4; straight through tubing connectors SRTC-2; T-junction tubing connectors SRTC-3 and tubing end fittings for safe connection of capillary tubing.

Du Pont chromatographic systems have uniquely broad capabilities in areas of liquid chromatography ranging from quality control to trace analysis to gram-size preparative purifications. Instrumentation is available to operate effectively in all chromatographic modes of separation: partition, adsorption, ion exchange and steric exclusion. Modular instrument design ensures that changing analytical needs will not become obsolete in existing instrumentation. The company has incorporated the following innovations into its present range: true flow-feedback constant flow; programmable gradient elution with patented single-pump system of gradient control; simultaneous fluorescence/absorbance detection; automatic sampling; bonded packings and preparative columns for gram-size loadings. Equipment includes the 848 high performance flow controlled LC system with 833 precision controller accessory, the 838 programmable gradient electron accessory, the 830 research liquid chromatograph, and various injection systems, a variety of packings and columns; also several detectors, both fixed and multiwavelength, differential refractometers, fluorescence/absorbance detectors and the 837 spectrophotometer designed specifically for LC.

Circle No. 55 on Reader Enquiry Coupon

Varian introduces a low cost fluorescence detector for PPT trace analysis in liquid chromatography. Fluorichrom has been introduced for sensitive detection of both naturally fluorescent compounds and fluorescent derivatives. For compounds with high fluorescent quantum yields Fluorichrom can optimally measure minimum detectable concentrations (MDCs) 300 times lower than can be measured with absorption detectors. Typical Fluorichrom MDC values are: polynuclear aromatics in the 50 ppt range, amino acids, 25–75 ppt, and aflatoxins as little as 20 ppt. The photometer employs a unique dual filter system and 90° geometry to obtain low noise and high sensitivity. Two filters, rather than just one, are used at both the excitation and emission positions. The two filters reinforce one another in the cutoff regions minimising leakage and noise from unwanted light. Also, by collecting fluorescing radiation at 90° to the incident beam, noise from scattering is virtually eliminated. A broad selection of filters is available for Fluorichrom: bandpass, interference, or cutoff—for selectivity or for maximising cumulative fluorescent emission over a wide wavelength range.

Believing in OSTP's merits

President Carter last month sent Congress a proposal to reorganise the constellation of offices and advisory units which together constitute his immediate White House and Executive Office staff. The proposal is the first of many promised moves to streamline and prune the federal bureaucracy, a pledge which figured prominently in Mr Carter's campaign rhetoric. For the fledgling Office of Science and Technology Policy (OSTP), the most important outcome of the proposed reorganisation is that it will be kept in business.

That fact alone signifies that OSTP has made an impression in the Carter administration during its short lifetime, for it is widely acknowledged that the people who planned the reorganisation were initially disposed to recommend that the office be disbanded. According to Dr Frank Press, Carter's science adviser and director of OSTP, the reorganisers approached the office as disbelievers, but went away as believers in OSTP's merits.

One reason for that belief is that Press has established a close working relationship with other White House units and he seems to enjoy easy access to the President, a fact which adds considerably to his standing in the White House power structure. He attends Cabinet meetings and daily meetings of Carter's senior staff, and OSTP is always represented during budget negotiations between agencies which have responsibility for R & D and the Office of Management and Budget. In addition, OSTP has been called upon to undertake a raft of studies ranging from a review of dam safety regulations to a survey of basic research policies in mission oriented agencies. Clearly, OSTP has established a solid niche.

Nevertheless, the reorganisation plan does not leave OSTP entirely unscathed. It will remove a number of functions specifically consigned to OSTP in the legislation which established the office last year, and it will result in a reduction of OSTP's staff level from the congressionally authorised 32 positions to 22. The net effect of the pruning will be to preserve and perhaps even strengthen those provisions related to the day-to-day advice to the President and other White House units, while stripping away some responsibilities for analysing longer term issues.

Although those losses may seem like a small price to pay for retaining OSTP in the White House, they are cause for concern. In fact, there has recently been some grumbling from OSTP's chief sponsors on Capitol Hill, notably Olin Teague, chairman of the House Committee on Science and Technology, and Senator Adlai Stevenson, chairman of the Senate Commerce Subcommittee on Science, Technology and Space. Both have sent letters to the chairmen of the House and Senate Government Operations Committees, which will be reviewing the reorganisation plan, expressing concern at the potential loss of some of OSTP's functions.

Specifically, the reorganisation plan would relieve OSTP of the responsibility for preparing two reports, a five-year outlook identifying problems and issues likely to require attention in the years ahead, and a series of annual reports reviewing developments in science and technology and assessing selected government programmes. Both those tasks will now be undertaken by the National Science Foundation, which is probably as well equipped as OSTP to write such reports, but studies carrying a White House imprimatur would carry much more weight.

The reorganisation plan would also do away with the President's Committee on Science and Technology (PCST), a top-level advisory committee similar to the former powerful President's Science Advisory Committee. PCST was established by Congress primarily to conduct a two-year review of federal science policies and to recommend organisational changes in the federal bureaucracy dealing with science and technology. At the end of PCST's review, Carter would have had the option of keeping the committee as a permanent advisory body.

The committee will be scrapped chiefly because a White House unit is already looking at government reorganisation—having a separate committee looking into the organisation of science agencies was deemed superfluous. Nevertheless, the committee's demise will remove a potentially important source of outside opinion particularly on longer term issues which lie beyond the day-to-day matters facing the White House.

When Congress created OSTP last year, it gave it the dual role of advising the President and other White House units on issues involving science and technology, and of providing long range analysis of broad questions concerned with science and social policy. The reorganisation seems to have strengthened the first role by ensuring that the Science Adviser will have a secure place in the upper echelons of the White House. But the second function has been downgraded. □

Science in the Himalayas

Peter D. Moore, recently in India, finds some scientific surprises in the mountains

ANYONE who travels in India soon grows accustomed to the unexpected. Even so, the little town of Dehra Dun, nestling in the foothills of the Himalayas ten hours' train journey north of Delhi, will surprise the most hardened traveller, for it occupies an influential position in Indian science. It serves as a centre for research, training and exploration in such industries as oil and natural gas and in forestry, and it is also the base for the Northern Region of the Botanical Survey of India.

The most unexpected of these is perhaps the oil industry, especially when one considers the distribution of oil and natural gas exploitation in India. At present there are two major sedimentary basins yielding oil (see accompanying map), located at the eastern and western extremities of the subcontinent. In the east is the Assam-Arakan basin, which is being exploited by both the Indian Oil and Natural Gas Commission (ONGC) and by Oil India Ltd, in which the Indian Government and the British Burma Oil Company hold equal shares. At present Oil India is producing 3.08×10^6 tons annually from Assam, representing more than a third of India's total oil production. Further development of this field could double its output. In the west of India, in Gurarat, is the Cambay Basin, which extends from the coast to the gas-bearing strata of Rajasthan and south into the Gulf of Cambay. This field was discovered in the late 1950s and since then the offshore fields of the Bombay High have also been brought into production.

Crude oil production has risen from 259,000 tons a year in 1951 to a present output of about 8×10^6 tons. Greatest expansion was achieved between 1963 and 1969. At the same time annual consumption of petroleum products has risen from 3.9×10^6 tons in 1951 to a present level of about 23×10^6 tons. India is thus producing only one third of her oil needs.

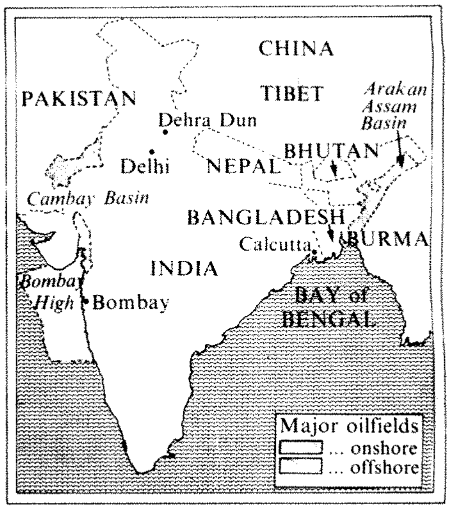
Oil consumption in India will undoubtedly continue to grow. Apart from her fuel requirements, the growth of the petrochemical and fertiliser industries will present an increasing demand. There is already talk of lining canals with polythene to prevent water losses, and even the possibility of covering whole fields. In fishing, clothing and domestic construction, particularly in the improvement of water supplies and sewerage, plastic products will contribute to efficiency and to health. Historically, many apparently profound influences have been passively absorbed by India and have been swallowed by the inertia of her ageless culture, leaving her unchanged. Will plastics really alter the face of India? One wonders whether the Indian's concern for the welfare of bovines will actually result in a plastic bullock cart fitted with pneumatic tyres—a suggestion recently made by Dr S. Varadarajan, Chairman of Indian Petrochemicals Ltd.

Growing demand

On the fertiliser side, the current production of about 1.5×10^6 tons of nitrogen has placed a growing demand upon crude oil. Many plants consume sulphur-rich fuel oil, which can be imported relatively cheaply because of the air pollution resulting from SO_2 production on combustion and because of the strength of the ecological lobby in the industrialised nations. India, like so many developing nations, does not yet feel in a position to afford the clean air which the developed nations now vainly seek.

What India also cannot afford is that its oil import bill should continue to rise. Great emphasis is now placed, therefore, upon the closure of the gap between home production and consumption of petroleum products. Optimistic predictions abound in India at present. Prospects for the development of existing fields, particularly the offshore drilling in the Bombay High, are good. Proven reserves on land in India are estimated at 700×10^6 tons, of which 200×10^6 tons are considered recoverable, while the Bombay High is thought to contain at least another 800×10^6 tons. N. B. Prasad, chairman of ONGC, considers that production from these major fields can rise to about 20×10^6 tons a year within the next four years, thus narrowing very considerably the gap between production and demand in the country.

The political dream of an India self-supporting in her oil needs, however, still demands further exploration and development. This is where the Himalayan town of Dehra Dun comes into the picture. In 1963 an Institute of Petroleum Exploration was set up with the aid of money from the United Nations Development Programme. The apparently strange choice of site (almost equally distant from both of the major oil producing areas) can be explained by the contemporary search for oil in the Himalaya foothills. In the fourteen years since the inception of this institute no reserves of a commercially viable nature have yet been discovered, thus leaving it stranded in a remote but scenic location which was once the summer playground of the British Raj.



Exploration and analytical research remain the prime functions of the Dehra Dun Institute. A comprehensive evaluation of the sedimentary basins of India is under way, no mean task given that it covers basin areas of 10^6 km² onshore and 320,000 km² offshore. The volume of chemical, geological and palynological data generated in the laboratories at Dehra Dun has necessitated the installation of an IBM 370/145 computer in the institute for rapid assessment of oil-bearing potential. Russian influence at the Institute has been and remains strong. The original UN representative at the establishment of the institute was a Russian and a team of scientists from the Soviet Union assists in research and analysis.

Forestry too

The Institute of Petroleum Exploration is not the only surprise awaiting the visitor to Dehra Dun. Just 6 km west of the town stands a most extraordinary and impressive building set in 445 ha of lawns and gardens. It houses the Indian Forest Research Institute. Built in 1929 and inaugurated by the then Viceroy of India, Lord Irwin, this institute is a monument to the economic importance of forestry in India. It began as the Imperial Forest School in 1884 and then expanded to encompass forest research. It now serves both a research and teaching function and houses a staff of 1,900.

As in many other countries, India has suffered badly from deforestation and the resultant soil erosion. This has reputedly come about particularly since Moghul times in north India. It is said (usually by Hindus) that the Mohammedans did not possess the same respect for vegetation as their Hindu predecessors. It is certainly true that vast areas of the Himalayan foothills have been stripped of forest and now only fragments remain. This has come about both as a result of intensive grazing and also the use of wood for fuel.

The varied topography in the region of Dehra Dun provides an ideal setting for a Forestry Institute. The steep slopes of the Lesser Himalayas take one up out of the sub-tropical climate of the plains and the Siwalik Hills into the cool temperate climate of the foothill ridges. Broad features of forest zonation accompany these altitude changes. It is thus possible for students at the Forest Research Institute to gain experience in a variety of forest conditions.

Besides the practical aspects of silviculture, the institute offers training and research facilities in such fields as entomology, paper technology, wood physics, timber mechanics and genetics. The main buildings house a vast museum and herbarium. The institute has served an important function in the development of techniques suitable for the conditions found in India. For example, the use of bamboo as a raw material in the manufacture of paper was pioneered here, as was the use of sugar cane waste. Bamboo, the poor man's timber and the standard material for scaffolding in India, represents a jungle to the taxonomist. There are about a hundred species and they flower only once, immediately prior to death, so that by the time you can identify them it is too late. Techniques for identification on the basis of culm sheaths and young bud structure are currently being worked upon, since identification is essential for the further development of bamboo management methods.

Besides the obvious products of forestry, timber and pulp, the Indian forests are rich in species which are economically important as a source of minor products. For example, the oil from sandalwood is an important earner of foreign exchange for India. The production of santonin from certain *Artemisia* species is an area which has recently received attention. The survey of Indian plants for potentially useful species is thus of considerable importance. The Forest Research Institute deals with woody plants, but what of the others?

Botanical survey

It comes as no surprise to find yet another institute tucked away in the suburbs of Dehra Dun, this time the headquarters of the Northern Circle of the Botanical Survey of India. This is a government organisation which is centred on Calcutta and which functions through four Regional Circles. The emphasis is upon plants as a national resource (in an economic rather than an aesthetic sense), but the bulk of the work is purely taxonomic. At present the flora of India has still not been fully described and the high Himalayas represent a particularly underworked area.

Because a major aim of the survey is the discovery of plants with a commercial potential, especially those with medicinal properties, the development of a herbarium of dried specimens is not enough; plants must be kept alive. The establishment of a botanical garden is therefore a priority and, as many of the more interesting plants derive from high altitude, the garden must also be sited in the hills. The British developed an upland botanic garden at Mussoorie (about 2,200 m) but this has now been abandoned as a scientific venture. A new garden has been established at Pauri (1,500 m) which will be used to maintain populations of high altitude plants and for experimentation. Such a venture may also prove to be valuable for the conservation of some rarer species, such as some of the orchids, and may also provide material for horticultural developments.

Perhaps the plant resources of the Himalayas will soon provide the basis for further commercial exploitation in the form of tourism. It still takes a considerable muscular effort to reach the Bhyundhar Valley (the 'Valley of Flowers') at 3,600 m but one can envisage changes coming about as India seeks more opportunities to earn foreign exchange. Although the Hindu pilgrims are prepared to trek on foot to their mountain shrines, the Western tourist will undoubtedly demand the development and despoilation of these remote areas. Conservatism, a right sense of priorities, or even sheer inertia may make India unwilling to pay the price. ☐

Cultivated terraces near Mussoorie in the Himalayas

EARTHQUAKES

Warning in time

Accounts of recent successful earthquake predictions in China have reached Western scientists. Colin Norman reports

THREE successful earthquake predictions were made in China last year, and warnings were issued in time to evacuate people from hazardous buildings in the threatened area. But there were also some failures. A number of false alarms were issued, and Chinese scientists failed to predict the devastating earthquake which levelled the city of T'angshan in July last year.

Those recent successes and failures were discussed for the first time by Chinese scientists who attended an international meeting on earthquake prediction sponsored by UNESCO (the United Nations Educational, Scientific and Cultural Organization) in Paris late last month. According to American scientists who attended the meeting, the Chinese were frank in their discussions and provided much previously unreported information on their methods.

Interest in China's earthquake prediction programme has been intense ever since it became known in the West that Chinese scientists had accurately predicted a major earthquake which struck the city of Haicheng in February 1975. That prediction led to evacution of the city and it is credited with saving many lives.

The latest successful predictions, according to Robert L. Wesson, a seismologist from the US Geological Survey who attended the UNESCO meeting, involved three earthquakes in 1976 of about magnitude 7 on the Richter Scale. They occurred in Yunnan Province on 29 May, in Szechuan Province on 16 August, and in the Szechuan–Yunnan border region on 7 November.

Wesson reported that in each case, Chinese scientists made long-term predictions that an earthquake would occur. Based on a variety of geophysical and magnetic anomalies, the long-term predictions were used as a basis for more intense monitoring in the threatened area, and for disaster planning. They were, however, not made public.

Public warnings that an earthquake was imminent were issued only on the appearance of foreshocks—minor tremors which sometimes precede major quakes. The public warnings, according to Wesson, were accompanied by evacuation of people from potentially hazardous buildings. The appearance of foreshocks in the Haicheng area was also used as the trigger for issuing an earthquake warning there in 1975.

Major earthquakes frequently strike abruptly, however, with no foreshocks, and thus imminent hazard warnings may not be issued in time. That seems to have been the case with the T'angshan earthquake. Wesson said that the Chinese had made a medium-term prediction of a quake in the area which had underestimated the magnitude of the event and no imminent warning was issued. In the past, Chinese officials have been reluctant to discuss the T'angshan earthquake, which killed more than 600,000 people.

Wesson also said that the Chinese scientists at the UNESCO meeting admitted that several false alarms have been issued, although their success rate was not revealed. According to Dr Jack Savage, a geophysicist who has visited China, Chinese scientists have acknowledged issuing false alarms before, but they argue that they would prefer to issue warnings whenever necessary rather than risk the consequences of an unpredicted major quake. □

DENMARK

Big science in a small country

A new nuclear physics project is under consideration in Denmark. Sven Godtfredsen reports

THE fate of experimental nuclear physics at Denmark's Niels Bohr Institute is in the process of being decided. An accelerator project now under consideration by the Ministry of Education marks an attempt by the institute to proceed on its own following the failure of an attempt at Scandinavian collaboration. But the enormous costs mean that the matter is likely to become a central issue in Danish science policy.

The project, known as the Danish heavy ion project, was submitted to the Ministry of Education, by the Danish Council for Scientific Policy and Planning. It involves building a 20MV or 25MV tandem accelerator. The total cost of the project will include the cost of building the accelerator, estimated at DKr115 million or DKr86 million depending on the choice of terminal voltage, and the DKr3 million increase in grants to the institute for operating the accelerator (£1 = DKr10.4). Financially speaking, the project is breathtaking compared to expenditure on other natural science projects in Denmark. Grants from the Danish Natural Science Research Council (DNSRC) whose function is to finance and to some extent lead Danish research in the natural sciences, amounts to only DKr25 million a year.

The DNSRC gave its view on the project last May in a report called *The Future of Nuclear Physics in Denmark*. Apart from examining the scientific content of the heavy ion project, the report reviews it in relation to broader issues—specifically, Danish participation in CERN, the attempts to establish collaboration in nuclear physics between the four Scandinavian countries (the NORDAC project), the possibility of collaboration between the institute and the heavy ion laboratory in Darmstadt, and of course, the particular financial aspects of nuclear physics in Denmark. But the question really concerning the DNSRC is how long a small country like Denmark can run its own programme in such an expensive branch of natural science.

This question is not new. It was asked in 1970 when the Niels Bohr Institute needed to renew the 9 MV tandem accelerator, and inspired nuclear physicists from the four Scandinavian countries to discuss the possibility of building a major heavy ion laboratory in the North. The idea was elaborated into the NORDAC project, which the DNSRC strongly recommended and which received financial assurances from the Danish government. Unfortunately the other Scandinavian countries were unable to back the project. Since then the institute has used the heavy ion tandem accelerator in Darmstadt for most of its nuclear physics experiments. But scientists at the institute feel that this approach weakens the contact between experimental and theoretical nuclear physics, traditionally the institute's strong feature.

There is little reason to believe that the NORDAC project is any more likely to happen now, so the Niels Bohr

Institute has decided to try to proceed on its own. Once again it has obtained full support from the DNSRC which argues that the proposed accelerator must be a national as well as an international asset. Current research at the institute needs an accelerator which provides a beam of very high energy heavy ions with good ionoptic properties and of very precise energy which can be varied rapidly. At present these requirements are only fulfilled by heavy ion tandem accelerators three of which are currently under construction: at Oak Ridge, Tennessee, in the USA (25 MV), at Daresbury in Britain (20 MV, which can be upgraded to 30 MV) and at the Atomic Energy Research Institute in Japan (20 MV). The DNSRC believes that the kind of nuclear physics research which can be undertaken with these accelerators is so fruitful that more accelerators than these three instruments will be needed in the near future.

Both the DNSRC and the Danish Council for Scientific Policy and Planning stress that the accelerator is required to continue the close interplay between theoretical and experimental work and "to sustain the status of the Niels Bohr Institute as a centre of excellence". Without the 25 MV or the 20 MV tandem they believe the institute will stagnate; with it they believe the institute will use its capabilities to provide results "with consequences for the world picture presented by modern physics". □

COMECON

- The thirty-second Session of the Comecon Permanent Commission for the Peaceful Uses of Atomic Energy which took place recently in Budapest discussed the long-term draft plan for fuel, energy and raw materials, cooperation in the use of radiation in industry, agriculture and environmental protection, the improvement of anti-radiation precautions and protection, and the disposal of radioactive waste. Also considered was the significance of cooperation in nuclear power for the overall coordinated plan for integrating the member countries' economies. To celebrate the thirtieth anniversary of Comecon, the Commission will publish, in 1979, a book entitled *The Peaceful Atom in the Countries of Socialism*.

Long-term energy and raw materials needs was also one of the themes of the recent meeting in Havana of the Permanent Commission on Power. In addition to discussing the long-term development of the unified power grids of the continental members of Comecon, special attention was paid to the particular needs of Cuba. A broad programme of new investments includes the construction of the first nuclear power station and the installation of transmission lines of higher tension than the present 220V. Cuba is already involved in a number of Comecon bilateral agreements for cooperation in nuclear and conventional energy with the USSR, East Germany, Hungary and Poland. According to J. L. Beltrami, the Cuban Minister of the Electrical Industry, it hopes to conclude similar agreemnts with the other member countries in the near future, and to establish a programme of multilateral cooperation.

- A new Comecon international organisation, Agroinform, has been established to coordinate scientific and technical information on agriculture and forestry. It is part of a general policy of integrated information systems for the Comecon bloc, based on the International Scientific and Technical Information Centre of Moscow, to coordinate the activities of member countries in collecting, selecting and processing information. So far Agroinform has dealt mainly with details of organisation and administration; this autumn, however, its International Council will meet in Prague to discuss the system's technical details. For the present exchange of agricultural information remains largely a matter of bilateral negotiations, such as the recent agreement between the Polish Academy of Sciences and the Czechoslovak Federal Ministry of Agriculture and Food covering research into the genetic and environmental factors affecting the quality of meat.

- During the past few years, Czechoslovak industry has made massive capital investments in plant and machinery purchased from abroad. By the end of 1976, some 15,000 million Czechoslovak crowns had been spent on equipment from 'capitalist' countries, a sum which theoretically is to be recouped by ever-increasing exports. But unfortunately, some 58,000 million crowns worth of the imported equipment is still standing idle, due to delay in the construction of factories to house it. At one chemical plant, Chemiceluloza, 200 million crowns worth of imported equipment is reportedly waiting at the construction site and cannot be installed until late in 1978.

- A second Polish Antarctic research station will come into operation during the coming southern summer. Named the 'Antoni Boleslaw Dobrowolski' station, it was handed over to Poland by the Soviet Union in 1959 but has not been used until now because of a lack of funds. Situated at the Bunger Oasis, 300 km from the coast and 4,000 km from the existing Polish 'Henryk Arctowski' station on King George Island, it will conduct mainly geophysical and meteorological research sponsored by the Geophysics Institute of the Polish Academy of Sciences.

The opening of Dobrowolski station is part of a general increase of Polish activity in the Polar regions. After an intensive programme of geophysical, meteorological and oceanographic research at the Arctowski station last summer, a team of 19 scientists manned it for the present winter. Meteorological data from the station forms an important link in the weather-forecasting network based on the Soviet Molodezhnaya station.

- A detailed programme has been worked out for joint Comecon research into the use of solar energy. The programme is largely based on Soviet experience in this field; at present, about 100 small solar power stations are operating in the Soviet Union, and are expected to operate without interruption for more than 10 years. According to the Soviet newspaper *Trud*, these stations have one great disadvantage—the high cost of the electricity produced.

Vera Rich

IN BRIEF

JET suffering

The European Community's Joint European Torus (JET) fusion project, now costed at almost £100 million at January 1977 prices, is "overdue" and "suffering from serious lack of decision on vital matters", according to Bas Pease, the director of the Culham Laboratory near Oxford, where the JET design team is based. Writing in the laboratory's 1976 annual report, Dr Pease says that prospects of future European international cooperation depend on confidence that technically sound projects like JET can be carried out. The report also says that uncertainties over the site have made it difficult to plan certain work on JET.

Marine responsibilities

Those who believe that very few subjects are the specific responsibility of a single government department in Britain are vindicated by the contents of a publication prepared by the UK Government's Interdepartmental Committee on Marine Safety. Entitled *Marine Activities. Guide to the responsibilities of government departments and agencies,* the booklet shows, that marine pollution involving oil discharges, is the responsibility of the Department of the Environment when the discharges are from land or offshore installations within the 3-mile limit, but fall under the Department of Energy outside that limit. Occupational health and safety are the responsibility of the Health and Safety Commission. The booklet is published by the Department of Trade

IAEA's report

The growing uncertainty over the future of nuclear power in some industrialised countries is reflected in the International Atomic Energy Agency's annual report for 1976. It was partly responsible, the report claims, for orders for new nuclear plant falling from 53,000 MW in 1974 to 11,000 MW in 1976. The IAEA's total estimated regular budget for 1978 is $48.8 million (£1=$1 74). Expansion is planned for some areas of its work.

Frugal farming?

KENNETH MELLANBY

WITH the possibility of a world shortage of energy within the next twenty five years, many people are concerned lest this should jeopardise our food supplies. They are told that modern farming is 'energy intensive', producing fewer calories to eat than are expended in their production—in cultivations, manuring and harvesting—notwithstanding the stored solar energy obtained by photosynthesis.

It is sometimes therefore suggested, particularly by some who call themselves 'ecologists', that we should return to more primitive farming systems, or even to the practices of the pre-agricultural hunter and gatherer. The bushmen of the Kalahari desert in South Africa are often cited as examples of global frugality, living with the minimum disruption of the natural ecosystem, and taking out much more energy than they put into it. It is generally forgotten that this type of life is only possible with small and sparse populations; it is thought that the whole of Britain could only feed some five thousand people before the introduction of arable farming. The whole world might support about a million.

Without going so far back, it is perhaps worth looking at some of the farming methods used fifty or a hundred years ago. Thus if oil is getting scarce, it may be logical to use more horses. An analysis of the effect of such a change gives the surprising result that there would be an increase, not a decrease, in energy consumption.

In Britain today all the tractors, combine harvesters and other farm machinery use about 1% of our total oil consumption (under one million tons coal equivalent), even allowing for the fuel consumed in the factories making the machines. In 1939 we had about a million working horses on our farms, but we would need at least double that number to harvest the vastly greater crops grown today. These horses would need to be fed every day of the year, not (like a tractor) only when they were working. It used to be said that a horse needed three acres of land for its support, but much of this was probably rough grazing. Nevertheless they would need some grass, and possibly as much as two tons of oats, or its equivalent in other grain, per horse per year. This would mean that more than two million acres of the best farm land would be needed to support the horses, and so would be lost for the production of human food.

The energy equation is equally disastrous. The calorific value of the horses' food would be at least four times that of the fuel powering the modern tractors, which do the work so much more quickly, and so enable the farmers to take advantage of Britain's changeable weather. In a bad year it is likely that, working with horses, much of the harvest would never be gathered in, and the land would seldom be cultivated in time for the next sowing.

Then if we went back to horse power, the human workforce would need to be doubled or trebled. Some people would welcome this, believing that it might decrease unemployment and reinvigorate village life. But are we prepared to pay all these farm workers the sort of wages they would expect from industry, when there would be a fall, rather than an increase, in food production? And where would they live? We have virtually abolished the 'tied cottage' reserved for farm workers; the houses are occupied by commuters, the retired and weekend visitors. On a purely arable farm the employees can travel to work, but where animals, including horses, are kept, the staff must live close at hand.

The main reason modern farming appears to use so much energy is not its machinery, but the inefficient food conversion of its intensively kept livestock, which waste over 90% of the food they eat. Our farm animals consume about forty times the energy used by our tractors. Horses, like other animals, are poor converters of energy. The surprising thing is that our highly mechanised farming techniques in Britain use only some 3% of our total energy budget. If yields are to be maintained, a return to old techniques and to the use of horses would greatly increase the input of energy down on the farm.

news and views

The return of whole-mantle convection

from Peter J. Smith

'THOUGH it has been clear for ten years that the motion of plates must involve flow in the mantle below, nothing is yet known with certainty about the form this motion takes.' This recent remark from McKenzie (*Geophys. J.*, **48**, 211; 1977) is indisputably true but conceals some interesting swings of opinion. When mantle convection was first proposed by Holmes (*Trans. Geol. Soc. Glasgow*, **18**, 599; 1931) and others it was clearly envisaged as a process taking place throughout the whole of the region between the crust and core. By the 1960s, however, when the hypotheses of continental drift and seafloor spreading were being combined and extended into the theory of plate tectonics, the idea of whole-mantle motion had already fallen into considerable, though not complete, disfavour. Some Earth scientists had produced what they felt were valid reasons for supposing the lower mantle to be immobile, and others had greatly increased our knowledge of the thin mobile layer immediately below the lithosphere. It was perhaps inevitable, therefore, that the asthenosphere should come to be regarded by many workers as the key to the lithospheric movements above.

But a year or so ago the idea of convection throughout the mantle (or, more correctly, throughout that part of the mantle below the lithosphere) began to regain favour; and this trend continues. Gough (*Earth planet. Sci. Lett.*, **34**, 360; 1977), for example, has come down in favour of whole-mantle convection on the basis of a study of the geoid. When departures of the geoid from the flattened Earth spheroid are plotted on a sphere, a single zero-elevation contour is found to divide the surface into two nearly equal zones with positive and negative elevations respectively. Moreover, these two zones are interleaved rather like the strips which cover a tennis ball. The areas covered by the zone of positive elevation include the western Pacific, most of Australia, the Arctic, the North Atlantic–European region, western South America, the South Atlantic and the South Indian Ocean. The areas covered by the zone of negative elevation, on the other hand, include much of Asia and the Indian Ocean, the Antarctic, North America, the Brazilian shield, the eastern Pacific and the western Atlantic.

What does this antisymmetric pattern mean? To Gough it suggests mantle-wide convection, the scale of the two zones being too great to be attributable to the effects of near-surface structure. As Gough envisages it, upward currents in the mantle would exist beneath all areas of negative elevation (low geoid), there would be downward currents beneath areas of positive elevation, and horizontal flow would occur across the zero-elevation contour (one way near the surface and the other way at the base of the mantle). In other words, by this interpretation the geoid represents 'whole-mantle convection in a single three-dimensional cell.'

If this is right, it then raises the question of the extent to which mantle-wide convection influences the motion of the lithosphere. Gough sees some 'encouraging relationships' between his model and actual plate behaviour; for example, the model predicts rising currents beneath the East Pacific rise and downward flow beneath the western Pacific subduction zones. On the whole, however, he is inclined not to expect close correlations between global convection and plate motion, arguing that lower mantle behaviour will be partially decoupled from the lithosphere by the intervention of the asthenosphere. In other words, the existence of mantle-wide convection would not preclude shorter wavelength convection in the asthenosphere with perhaps greater influence on the overlying plates.

But this rather defensive posture is not shared by Davies (*Geophys. J.*, **49**, 459; 1977) who claims it to be 'unlikely that the lower mantle is *not* involved in motions related to plate tectonics.' Davies, too, draws attention to the possibility of small-scale flow in the upper mantle but he clearly regards such motions as perturbations on large-scale mantle-wide convection, thus imputing to them relatively less importance than does Gough. It would be misleading to make too much of this difference in emphasis, for both authors share the conviction that the limitation of convection to the upper mantle is unlikely. Davies is able to be somewhat more positive, however, because his conclusion is based on the study of whole-mantle convection models which, although simplified, can account qualitatively for the large horizontal scale of plates, the imperfect correlation between plate speed and the amount of attached descending slab, the motion of plates with no attached slab, and the opening of the Atlantic in particular.

What Davies's study of simple layered-fluid models shows is that thermal convection would be confined to the upper mantle only if the lower mantle were at least 10,000 times more viscous than the upper mantle. And even if the mantle were to play only a passive part in plate dynamics, the flow induced by the moving plates would fail to penetrate the lower mantle only if the viscosity of the lower mantle were at least 1,000 times greater than that of the upper mantle. Moreover, a shallow low-viscosity layer would have to be about 10,000 times less viscous than the mantle beneath for flow to be confined to it. In other words, it would appear that mantle-wide flow, whether induced thermally or by moving plates above, can only be prevented by extreme viscosity contrasts in the mantle.

Traditionally, of course, such contrasts have been widely accepted, or, as Davies puts it, 'speculations on and

---

Peter J. Smith is a Reader in the Department of Earth Sciences at the Open University.

models of mantle flow associated with plate tectonics have been dominated by the concepts of an elastic, high-viscosity lithosphere, a relatively low-viscosity asthenosphere, and a high-viscosity mesosphere.' Indeed, as far as the high-viscosity lithosphere and lower-viscosity asthenosphere are concerned, the tradition persists; the existence of these features is not seriously in doubt. What is at issue, however, is the viscosity of the lower mantle and its contrasts with, on the one hand, the viscosity of the asthenosphere and, on the other, the viscosity of the rest of the upper mantle below the asthenosphere.

To cut a long story short, several reasons have been adduced in the past for supposing the viscosity of the lower mantle to be many (for example, five or more) orders of magnitude greater than that of the asthenosphere, a view which appeared to have majority support until quite recently. But as Cathles's extensive studies have shown (*The Viscosity of the Earth's Mantle*, Princeton University Press, 1975), there are apparently equally good reasons to suppose that the contrast is much less. Cathles's own version is that the mantle has a fairly uniform viscosity of about 10^{22} poise throughout, apart from a thin channel (the asthenosphere) in the uppermost mantle which has a viscosity of about 0.4×10^{21} poise. It is difficult to say whether or not this view of mantle viscosity has become the new consensus; what can be said without fear of dispute is that the low-contrast mantle is now more popular than it was a few years ago and that it is now more fashionable to debunk arguments in favour of the high-viscosity lower mantle.

This clearly strengthens the case for mantle-wide convection, especially in the light of Davies's results. But what of the other traditional arguments against whole-mantle convection? In a very useful review section Davies looks at all the main ones and concludes in the light of recent information that none is of compelling validity. It has been suggested many times in the past, for example, that there may be chemical composition gradients in the mantle involving changes in mean atomic weight—obviously a situation which would be difficult to reconcile with the mixing brought about by whole-mantle convection. But as Mao (*J. geophys. Res.* **79**, 5447; 1974) and others have shown, the particular observations which led to the invocation of atomic weight changes can be explained at least as reasonably in other ways. Obviously this does not rule out the existence of chemical non-uniformity but it weakens the ability of such non-uniformity to stand as an argument against mantle-wide convection.

The evidence for the presence of phase transitions in the mantle, on the other hand, is much stronger, which raises the questions of whether phase boundaries can persist in the face of convective mixing and of whether the persistence of such boundaries may prevent convective flow across them. The available information here is conflicting, for much depends on the precise conditions in the mantle. Davies concludes, however, that the case for saying that phase transitions will prevent whole-mantle convection is suspect at best, although such transitions could well modify the pattern of convective flow. Likewise, the case for excluding the lower mantle from involvement in plate dynamics on the grounds, among others, that earthquakes do not occur below about 700 km is also dubious, for there are ways of explaining this lack of seismicity without assuming that descending lithosphere fails to reach beyond this depth.

In summary, then, Davies has presented what is probably the most convincing case yet in favour of convection throughout the mantle below the lithosphere, or at least the most convincing case for not rejecting whole-mantle convection quite so easily as it has often been rejected in the recent past. Nor is he alone. The support from Gough has already been mentioned, but there is more. Jones (*J. geophys. Res.*, **82**, 1703; 1977), for example, has suggested that long-term variations in the frequency of reversal of the geomagnetic field may be the result of fluctuating temperatures at the core-mantle boundary caused by convection in the lower mantle. And perhaps more importantly, Dziewonski *et al.* (*J. geophys. Res.*, in the press) are about to show that the large-scale seismic velocity anomalies detected in the mantle, including the lower mantle, by Niazi (*Bull. Seismol. Soc. Am.*, **63**, 2035; 1974) and others correlate with long-wavelength components of the gravity field—an observation which O'Connell (*Tectonophysics*, in the press) will relate to mantle motions. It would seem that the few people (for example, Runcorn) who have maintained their belief in mantle-wide convection for many years, if not decades, are to be vindicated, or at least are to see their views become fashionable again. ☐

Bed bugs and hepatitis

from Arie J. Zuckerman

ALTHOUGH much has been written during the past few years on all aspects of human viral hepatitis, and hepatitis B in particular, it seems that this infection still has some epidemiological surprises to spring. The latest is a report by Willis *et al.* (*Lancet* **ii**, 217; 1977) that the bed bug could be a vector of hepatitis B.

With some 120–176 million carriers worldwide, the importance of hepatitis B cannot be overemphasised. In regions such as northern Europe, North America and Australia, where infection is relatively uncommon (a carrier rate of ~ 1 in 100), transmission is chiefly through inoculation of blood and blood products, although hepatitis B can also be transmitted sexually and in other body fluids such as saliva, menstrual discharge, breast milk and semen. In areas where infection is relatively common such as parts of tropical Africa, South East Asia and the Far East (with a carrier rate of 10–20% of the population), transmission by direct inoculation of blood or blood products is not enough to account for the higher rate of infection. The modes of transmission of hepatitis B in the tropics are similar to those in other parts of the world, but additional factors may be of importance including traditional tattooing and scarification, ritual circumcision with unsterile instruments and repeated biting by blood sucking arthropod vectors, and in particular mosquitoes (or flying-pins; *Nature* **239**, 72; 1972) and bed bugs.

Review of the available evidence on the role of biting insects in the spread of hepatitis B shows that the results of preliminary investigations are conflicting. Hepatitis B surface antigen, which is one marker of the virus, has been detected in several species of mosquito, which have been trapped in the wild or fed on infected blood artificially, but no convincing evidence has been obtained either of replication of the virus or of its persistence after digestion of the blood meal. The very real possibility of mechanical transmission by mosquitoes nevertheless exists, for example as a result of interrupted and consecutive feedings particularly in areas with a high prevalence of hepatitis B (*Tech. Rep. Ser. Wld Hlth Org.*,

Arie J. Zuckerman is Professor and Director of the Department of Medical Microbiology and the WHO Collaborating Centre for Reference and Research on Viral Hepatitis at the London School of Hygiene and Tropical Medicine.

The bed bug, *Cimex lectularius* which lives in cracks and crevices in the house, especially in beds.

Photo: C. James Webb, London School of Hygiene and Tropical Medicine.

No. 602; 1977). Bed bugs live more intimately with man than do mosquitoes, take blood meals and could transfer blood and hepatitis B virus from one occupant of a bed to another. Brotman and her colleagues (*Lancet* **i,** 1305; 1973) collected bed bugs from dwellings occupied by prostitutes in the Ivory Coast and detected hepatitis B surface antigen in 1 (5.6%) of 18 pools of engorged bed bugs of the species *Cimex hemipterus.* In a laboratory study, Newkirk *et al.* (*Gastroenterology,* **69,** 982; 1975) artificially fed *Cimex lectularius* bed bugs on blood from a patient with acute hepatitis B. Hepatitis B surface antigen remained detectable in the bed bugs for over 4 weeks, and juvenile bed bugs contained antigen after moulting, at a time when the bug usually starts to search for a host and will refeed. In the course of another investigation, carried out in Senegal by Wills *et al.* (*op. cit.*) bed bugs were collected on four separate occasions from bedding in the huts of villagers. All the bed bugs were identified as *Cimex hemipterus,* the predominant species in West Africa and other tropical areas. Hepatitis B surface antigen was detected in unengorged nymph and adult bed bugs in each of the first three collections. Three out of 28 specimens were antigen-positive in the first collection and 3 of 17 specimens were positive in the second collection. In the third collection, 6 out of 9 bed bugs were positive when the bed occupant was known to be hepatitis B surface antigen-positive. The antigen was also detected in 3 out of 89 bed bugs of the fourth collection kept alive without a blood meal for 30 days. Of particular interest was the finding of the *e* antigen, which is a marker of infectivity of hepatitis B virus (see *News and Views* **263,** 374; 1976), in 1 engorged and 1 unengorged bed bug. These newest reports are the highest field infection rates with markers of hepatitis B virus reported so far in any insect species. Clearly bed bugs feeding on the occupants of the same bed could amplify the risk of hepatitis B infection, and this mechanism may provide an unromantic form of connubial spread of infection (Blumberg *Science* **197,** 17; 1977). There is undoubtedly a need to examine closely and objectively these and other blood-sucking insects, and the entire matter deserves further epidemiological and experimental investigation. □

Multispecific antibodies

David S. Secher

THE classic work of Landsteiner (*The Specificity of Serological Reactions,* Dover, New York, revised ed., 1962) in the first half of this century demonstrated that antisera have a unique specificity. In addition to recognising and discriminating between most foreign molecules, a man (or other vertebrate) can recognise newly synthesised organic chemicals which could not have been encountered during evolution. It has often been assumed that the exquisite specificity of antisera is a reflection of a similar degree of specificity in the antibody molecules that make up that antiserum. This, of course, would require the potential production of a number of antibodies equal to the number of specificities (perhaps 10^6–10^8). An alternative explanation of the high specificity of antisera which has been favoured by a number of immunologists was stated particularly clearly by Talmage in 1959 (*Science* **129,** 1643). He suggested that each constituent antibody species in an antiserum (a normal antiserum is almost invariably a complex mixture of many different antibody species) is capable of binding to several different antigens. The pattern of such cross-reactions will be different for different antibodies and each one will be effectively 'diluted out' in the whole antiserum. The only strong binding will be to the antigen that all the antibodies can recognise, namely the original, immunising antigen. In this way a highly specific antiserum may be made up from a population of much less specific antibodies. More recently Inman has developed this hypothesis in considerable mathematical detail (in *The Immune Systems* (eds Sercarz, Williamson & Fox) Academic, New York, 1974).

Until recently there was little experimental data to favour this hypothesis and the observation of more than one antigen binding to an antibody (or to a myeloma protein) was assumed to arise from structural similarities between the two antigens (see for example Michaelides & Eisen *J. exp. Med.* **140,** 687; 1974). Over the past few years Frank Richards and his collaborators at Yale University School of Medicine have shown that the binding of two antigens (dinitrophenyl (DNP) and vitamin K$_3$) to the mouse myeloma protein MOPC 460 takes place on two spatially distinct sites in the immunoglobulin molecule. They have argued that this is therefore an example of multispecificity of the immunoglobulin and not due to a cross reaction between the antigens (Richards *et al. Science* **187,** 130; 1975). Richards *et al.* extended the observation of multispecificity to include antibodies present in immune rabbit sera and, by the elegant use of isoelectric focusing in polyacrylamide gels, showed that a second antigen could also be 'functional' in the triggering of lymphocytes to produce antibodies (see Richards *op. cit.* for review). Again the binding of other antigens to anti-DNP antibodies was studied.

How much of a contribution to the repertoire of antibody specificities could such multispecificity make? Richards *et al.* estimated that 100 haptens (antigens) might bind to a single antibody. We have used a more conservative 'degeneracy factor' of 10 in discussing antibody diversity (Secher, Adetugbo & Milstein, *Immunol. Rev.* in the press). But these numbers are still just guesses and data from other systems are clearly required to indicate how general the phenomenon is.

Cameron and Erlanger (this issue of *Nature* page 763) have now examined the binding specificities of antibodies to adenosine-5′-phosphate (AMP) (see also *Immunochemistry* **13,** 263; 1976). Three fractions of anti-AMP antibody were purified by preparative isoelectric focusing from the serum of rabbits immunised with AMP–gramicidin S. The ability of these fractions to bind

---

David Secher is a member of staff at the MRC Laboratory of Molecular Biology, Cambridge, and a Fellow of Gonville and Caius College.

antigens other than AMP was studied by the inhibition of enzyme immunoassays and by three other binding or cytolysis assays. In contrast to Richards *et al.* who tested more than 300 ligands to find only 2, Cameron and Erlanger appear to have found at least 2 cross-reacting antigens out of the 11 tested. Vitamin K_3 (yet again!) and caffeine were found to bind to two out of three of the antibody fractions.

Cameron and Erlanger draw an analogy between the multispecificity of antibodies and the binding to enzymes of ligands unrelated to the main substrate. Some enzymologists might disagree with interpretation of the enzyme data but in any case the analogy is not very appropriate. Enzymes are homogeneous and so multispecificity in substrate binding could not enhance their specificity in the way that Talmage, Inman and others have proposed for antisera.

There is one practical consequence of the multispecificity concept that has so far escaped comment. Monoclonal antibodies produced by the cell fusion technique (Kohler & Milstein *Nature* **256,** 495; 1975) might have unexpected cross reactivities. No such observation has been reported but it is probably too early for anyone to have systematically looked for one.

A more fundamental question that has received surprisingly little attention is the relationship between antibody affinity and multispecificity. The 'best' antibodies bind their antigens with avidities of 10^{-9}–$10^{-7}\,\mathrm{l\,mol^{-1}}$ but so far multispecificity has only been observed in the $\geqslant 10^{-6}\,\mathrm{l\,mol^{-1}}$ range. It is clear from all the published data that as one examines antigens that bind more weakly to an antibody, there is a greater degree of cross reaction with other antigens. How much biological significance do these weaker interactions have? A normal immune response develops from low affinity IgM antibodies on the surface of cells in the primary response to high affinity IgG antibodies in the secondary response. Perhaps *in vivo* there is no single 'degeneracy factor' but a spectrum ranging from multispecific, low-affinity antibodies that enable an individual with relatively few cells to recognise a maximum of antigens, to monospecific, high-affinity antibodies. The best monoclonal antibodies may thus be highly specific after all! ☐

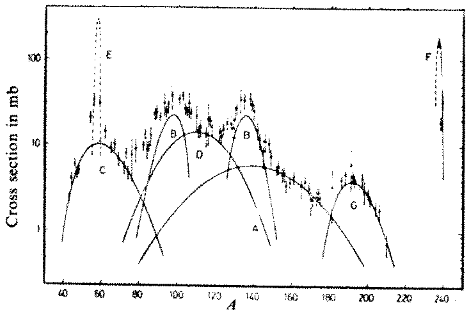
High-energy nucleus–nucleus collisions

from P. E. Hodgson

VERY many complicated processes can take place when two heavy nuclei collide at high energies, and these can be studied in a global way by measuring the mass distribution of the reaction products. A sufficient proportion of these products is radioactive, so this can be done by a radiochemical analysis of the target after irradiation. Such analyses give only the total cross sections for the production of the various fragment nuclei, and thus complement the detailed studies of individual reactions to particular final nuclear states.

Among the cross sections that can be determined by this method are those for fusion, when the two nuclei fuse together to form a compound nucleus, and quasi-fission, in which several tens of nucleons are transferred from one nucleus to another by a deep inelastic collision. Previous studies of the interaction of ^{40}Ar with ^{238}U and of ^{84}Kr with ^{238}U show that in the former case 55% of the total reaction cross section may be ascribed to fusion and 9% to quasi-fission, while in the latter there is only 4% fusion and 38% quasi-fission. These results suggest that as the mass of the projectile increases the probability of fusion falls rapidly. This is of great practical importance for those who are trying to make super-heavy nuclei by the collisions of heavy nuclei since it shows that the heavier the interacting nuclei the less likely they are to stick together, implying that heavy-ion experiments designed to produce superheavy nuclei are considerably less feasible than has been previously supposed.

As it is very important to verify this conclusion and confirm that this trend is indeed a universal one, a further measurement of the reaction products from the interaction of ^{56}Fe with ^{238}U has recently been made by Reus and collaborators from the Universities of Marburg and Manchester (*Phys. Rev. Lett.* **39,** 171; 1977). They find that 14% of the total reaction cross section is due to fusion, and 26% to quasi-fission, in line with the previous results.



Mass yield curve for the fragments from the interaction of 538 MeV ^{56}Fe with ^{238}U, analysed into components corresponding to various reaction mechanisms as described in the text.

The experiment was made by bombarding a target of ^{238}U with 538 MeV ^{56}Fe ions from the Manchester Linear Accelerator. After irradiation, the target was analysed radiochemically and the cross sections for the production of 173 nuclides were determined. The results are shown in the figure as a function of atomic mass, and show a number of distinct peaks which can be attributed to particular processes. Thus component A is assigned to fusion reactions (followed subsequently by fission) because the form of the mass yield curve in this region is consistent with that of a broad Gaussian distribution peaking at a mass value of 137±2, which is the estimated most probable mass for fusion–fission products in this interaction.

The component B has a shape and location indicating that it is due to low energy asymmetric fission following the quasi-elastic transfer of a few nucleons from one nucleus to the other. Component D is obtained by subtracting A and B from the total mass–yield curve, and its maximum corresponds to the mass number to be expected from the symmetric fission of nuclei formed by the deep inelastic transfer of several tens of nuclei between target and projectile, and so it is assigned to fission following quasi-fission, or sequential fission. Component G corresponds to those nuclei that are formed by deep inelastic transfer from target to projectile and survive sequential fission, and component C is the light quasi-fission partner. Finally the two sharp peaks at either end of the distribution, components E and F, are due to quasi-elastic transfer. They are not very well determined because many of the nuclides in these mass regions have half lives that are unsuitable for radiochemical assay. As a check on the whole analysis, the total cross section calculated for this interaction agrees with the sum of all the individual cross sections.

Integration of the cross section corresponding to each component enables the relative importance of the various processes to be found. The type of interaction that is likely to lead to the formation of superheavy nuclei is fusion of the interacting nuclei to form a compound system. This is of course expected to be rather unstable, so it soon breaks up, probably by fission. The important thing is that the compound system lives long enough for its

---

P. E. Hodgson is Lecturer in Nuclear Physics at the University of Oxford.

properties to be studied, and this is not the case for any of the other processes identified in this analysis.

This experiment, together with the two previous ones already mentioned, gives fusion cross sections of 620, 190 and 55 mb for the interactions of Ar, Fe and Kr with uranium, showing that the higher the mass of the projectile the lower the fusion cross section. Experiments designed to produce superheavy nuclei will thus have to rely on reactions initiated by projectiles much lighter than the target, and this severely reduces the range of nuclei that might be produced. ☐

Meteorite research old and new

from Robert Hutchison

The Fortieth Annual Meeting of the Meteoritical Society was held at Cambridge, UK on 24–29 July, 1977. The successful meeting attracted a dedicated band of 'amateurs' together with astronomers, astrophysicists, chemists, geologists, mineralogists and physicists.

REPRESENTATIVE of the 'old' is the search for isotopic anomalies in meteorites and their interpretation in terms of the birth of the Solar System. This is contrasted, for me, with 'new' studies on the asteroids of today, with new experimentation on meteorites and with the discoveries of new meteorites.

Representative of classic meteorite research was the discussion over the interpretation of ^{26}Mg excesses in meteorites. Over the past few years, this ^{26}Mg excess (from decay of ^{26}Al, half life, 740,000 years) has been interpreted in two main ways. One school considers that the excess was introduced into the Solar System in pre-solar refractory grains in which ^{26}Al was already extinct (D. D. Clayton, Rice University, Houston); the other considers that ^{26}Al was present in a pre-solar nebula, condensation of which produced high temperature mineral aggregates in which ^{26}Al decayed to ^{26}Mg; in these ^{26}Mg is proportional to the ^{27}Al/^{24}Mg ratio—the isochron relationship established by G. J. Wasserburg and co-workers at Caltech.

At the meeting Clayton argued that, because stars seem to form in cold gas–dust clouds, it must be assumed that all refractory elements were condensed at planet formation in the Solar System. Ca–Al–Ti-rich inclusions in the Allende meteorite, are, therefore, condensates from an expanding supernova. This is supported by the presence of volatile-rich rims around some inclusions; at least some of the rims predate incorporation into the meteorite. This argument was taken further by Schramm, Grossman and others (University of Chicago), who now propose that the products of two supernovae were ejected into the matter from which the Solar System formed. From the earlier came the r-process nuclides (^{244}Pu and ^{129}I for example) with half lives long enough to allow survival over about 10^8 yr, until the second, smaller supernova produced, among others, ^{26}Al. Enrichment in ^{16}O was due to destruction of ^{17}O and ^{18}O in the second event. The two stage theory is based on lack of correlation between isotopic anomalies in the light elements (O, Ne and Mg) and on isotopic homogeneity in the heavy elements (Sr, U).

A probably important discovery was discussed by R. N. Clayton, who, with T. K. Mayeda (both from the University of Chicago), found that the hydrated matrix of the unusually metal-rich carbonaceous chondrite, Renazzo, has terrestrial oxygen isotope ratios: for the first time we have a potential source for our oceans and atmosphere. Of similar importance is the discovery of a strongly heated carbonaceous chondrite, 'Mulga West' from Western Australia. Few ordinary chondrites contain water, most having been heated to temperatures of about 1,000 °C; in contrast, all previously known carbonaceous chondrites have low temperature mineralogy and so are often considered as originating in comets from the outer Solar System. The findings of R. A. Binns (University of Western Australia) and Australian and British coworkers now indicate that at least one carbonaceous chondrite parent-body was heated to the same extent as the (presumably) asteroidal parents of the ordinary chondrites. The question of the sources of meteorites was addressed by C. R. Chapman (Planetary Science Institute, Tucson). Considerable spectral and dynamic data have been accumulated on the asteroids, which can now be identified as potential sources of most meteorite types. However, problems still remain in relating the relative abundances of the different meteorite types to the relative abundances which could be produced from the asteroids.

Also in the 'new' category was a search for meteorites in Antarctica by W. A. Cassidy (University of Pittsburgh), E. Olsen (Field Museum, Chicago) and K. Yanai (Japanese Institute of Polar Research). With National Science Foundation support they spent two months near McMurdo Base. Their success in finding 11 meteorites has probably sparked off a new era in meteoritics, for it showed that the finding of hundreds of meteorites by the Japanese in the Yamato Mountains was not just a flash in the pan. And meteorites found in 'blue ice' areas should be sterile, a fact noted by the organic chemist C. Ponnamperuma (University of Maryland), who did not give his paper as scheduled but was reportedly hunting meteorites in Greenland. Meteorites are normally named after places near where they are found; the lack of named geographical features in Antarctica therefore poses a serious problem in meteorite nomenclature. This was discussed by a Committee on Meteorite Nomenclature of the Meteoritical Society, whose conclusions will be communicated in due course.

Other papers of note included one by N. M. Evensen and colleagues (Lamont Observatory, New York) who confirmed earlier suspicions that rare earth elements (REE) in some chondrites are fractionated. This could be a blow to geochemists who normally use REE in chondrites as an 'unfractionated' standard for comparison with terrestrial rocks. A consortium study on the largely unshocked achondrite Serra de Magé provided a further enigma. M. Prinz and G. Harlow (American Museum of Natural History, New York) and their various collaborators showed that this stone cooled more slowly than any known basaltic meteorite; that its pyroxene minerals are similar to those in the huge, slowly cooled Stillwater intrusion of Montana. However, G. Lugmair and others (University of California, San Diego) used the Nd–Sm age determination technique to show that Serra de Magé minerals probably did not become closed systems until 4.52 Gyr ago. By that time several related meteorites had been cool, and sometimes fractured (by impact?), for over 100 Myr. This poses problems about the size and heat-source of the parent body.

The meeting did not concern itself with meteorites alone. Two sessions were on lunar studies and one covered 'Terrestial Impact, Craters and Tektites', the first three papers of which dealt with a large Russian impact structure (49°N, 59°E). It was a pity that no Russian attended the meeting, but western collaborators described this Zhamanshin structure as an impact crater some 15 km in diameter, with associated natural glasses related to tektites.

Finally, several papers relied on new,

improved technology and experimental techniques. Data from the ion probe were presented and in one study of a fine-grained iron meteorite a scanning device on a transmission electron microscope was used to obtain high resolution spot analyses across the interface between α (low-Ni) and γ (high-Ni) metal. J. I. Goldstein and coworkers at Lehigh University, Pennsylvania intend to apply this technique to experimentally produced structures in an attempt to measure diffusion rates at low temperatures (below about 600 °C). □

More light on enzyme control

from C. J. Lamb and R. K. Dudley

It has been said in these columns that 'Plant molecular biology is not dead, but is merely awaiting the attention of competent and dedicated biochemists', (*News and Views* **254**, 13; 1975). A recent illustration of the potential contribution that biochemical studies can make to the understanding of plant biology is given by the work of Klaus Hahlbrock and colleagues at the University of Freiburg on the photocontrol of phenylalanine ammonia-lyase (PAL) levels in parsley cell cultures. By looking at the production of PAL in cell-free systems they have been able to show that the increase in PAL production observed after illumination is due to an increase in translatable mRNA and not to activation of previously synthesised enzyme.

PAL catalyses the deamination of L-phenylalanine to trans-cinnamic acid, the first step in the biosynthesis of plant compounds based on the phenylpropane unit and including lignins, flavonoids and coumarins. Its activity increases greatly following illumination of various plant tissues and the enzyme has proved popular for studying the photocontrol of gene expression in higher plants. Unfortunately, many of these investigations have relied on the effects of the antimetabolites actinomycin D and cycloheximide, both of which have many different effects in higher plants. Furthermore, density-labelling studies of the phytochrome-mediated increase in PAL activity in mustard seedlings have produced conflicting results and there is considerable controversy as to whether in this case enhancement of PAL activity is caused by activation of previously synthesised protein or by increased *de novo* synthesis. Hahlbrock's contribution has been to complement antimetabolite and *in vivo* labelling experiments with a careful study of the synthesis of PAL in cell-free systems. The results obtained to date suggest that this approach will give insight into a number of fundamental problems in plant biology.

Early work (reviewed by Hahlbrock *Physiol. Veg.* **14**, 207; 1976) demonstrated that on irradiation with blue or ultraviolet light, previously dark-grown parsley cell suspension cultures accumulate a number of flavonoids concurrent with a large increase and subsequent decrease in the extractable activity of PAL. These responses are red/far-red reversible, but neither red nor far-red light has an effect without ultraviolet preirradiation, suggesting that the initial responses are not phytochrome-mediated. The ability of light to enhance PAL activity declines progressively, and after a few hours illumination further irradiation has no stimulatory effect. *In vivo* studies with actinomycin D and cycloheximide and labelling with ^{35}S-methionine and ^{15}N-ammonia indicated that PAL was synthesised *de novo* following illumination. The light-mediated changes in the apparent rate of synthesis of the enzyme were calculated from the time-course of changes in extractable PAL activity under various programmes of illumination, and the results interpreted as reflecting short-term light-mediated increases in the concentration of specific mRNA available for translation.

This hypothesis has now been investigated directly by study of the biosynthesis of PAL in cell-free systems. *In vitro* protein synthesis with polyribosomes from parsley cell cultures was relatively low with a homologous system, but an effective heterologous system was established by supplementing the parsley ribosomes with an extract from wheat germ (Schröder & Hahlbrock *Biochim. biophys. Acta* **366**, 454; 1974). The rate of synthesis of PAL was determined by incorporation of ^{35}S-methionine into protein precipitable by a rabbit antiserum prepared against the purified enzyme (Schröder, Betz & Hahlbrock *Eur J. Biochem.* **67**, 527; 1976). Analysis of the immunoprecipitate by disc gel electrophoresis in the presence of dodecylsulphate revealed small amounts of the complete enzyme subunit (molecular weight 83,000) and relatively large amounts of shorter peptides which were also immunologically characteristic of the enzyme; an extra check by tryptic fingerprinting would have been desirable.

The capacity for PAL synthesis was much greater with polyribosomes from irradiated cells compared with those from dark-grown cells and the observed changes in the rate of PAL synthesis closely corresponded with those previously calculated from changes in the level of extractable PAL activity. The possibility that the increased capacity for PAL synthesis reflects changes in the amount or activity of ribosome-bound factors rather than changes in the level of translatable mRNA has been ruled out by extracting the RNA from parsley polyribosome preparations with chloroform/phenol and using this extract as a message in a rabbit reticulocyte lysate (Ragg, Schröder & Hahlbrock *Biochim. biophys. Acta* **474**, 226, 1977). Synthesis of PAL could only be detected using RNA from light-treated cultures. This is the first report that a mammalian cell-free system will accept a plant message for translation, and is especially interesting since PAL is an enzyme of plant secondary metabolism and is not found in animals.

These studies demonstrate an increase in the level of translatable PAL mRNA in response to illumination, but is this a result of more message being produced, or less being destroyed, or to pre-existing message being made available for translation, or indeed to a combination of these possibilities? To answer this will require purification of the PAL mRNA, a daunting task as the message is likely to be only a tiny proportion of the total RNA extracted. However, enhancement of the level of PAL activity is accompanied by concurrent increases in the subsequent enzymes of the pathway and using Hahlbrock's approach it should be possible to analyse the mechanisms whereby coordinated gene expression in higher plants is achieved in response to environmental stimuli. Of immediate interest is the phytochrome-mediated stimulation of phenylpropanoid biosynthesis in intact plants. The regulatory mechanisms may well differ from those observed with cell cultures undergoing rapid cell division and nucleic acid biosynthesis. □

review article

Why the genome does not congeal

J. Maynard Smith

* School of Biological Sciences, University of Sussex, Falmer, Brighton, Sussex BN1 9QG

Since the genes in any given organism have evolved together to produce an adaptive phenotype, one might expect that rearrangement by chromosomal recombination would be maladaptive and thus wiped out by natural selection. This article reviews various theories that explain why, on the contrary, recombination is almost universal.

TEN years ago, Turner[1] asked "Why does the genome not congeal?" That is, why do organisms not evolve a single large chromosome, with no chiasmata, so that genes inherited from one parent, father or mother, are passed on without recombination to a child. This question is related, of course, to that of why organisms reproduce sexually rather than parthenogenetically[2]. The argument against recombination, crudely, is this: if an individual has survived to breed, it is likely to carry a set of genes which combine well together, and recombination will therefore have the effect of breaking up sets of co-adapted genes.

In fact, there are good theoretical reasons for expecting natural selection to reduce recombination. Thus suppose that a population has reached genetic equilibrium under selection in a uniform environment; that is, gene frequencies at all loci have reached their stationary equilibrium values under selection. Then either the population will be genetically monomorphic, in which case recombination is selectively neutral, or (as almost all natural populations are) it will be genetically polymorphic at many loci. In the latter case, selection is likely to be for reduced recombination.

Fisher[3] was the first to reach this conclusion. Serious mathematical work was started by Kimura[4], and has recently been reviewed by Lewontin[5]. The crucial question is whether there is 'linkage disequilibrium' in the population: that is, whether the alleles at different loci occur independently of one another. (Technically, suppose there are two alleles at each of two loci, say A,a and B,b. Let p_{AB} be the frequency in the population of the gamete AB, and similarly for p_{Ab}, p_{aB} and p_{ab}. Then the 'coefficient of linkage disequilibrium' $D = p_{AB}p_{ab} - p_{Ab}p_{aB}$; linkage equilibrium requires that $D = 0$.) The relevance of D is simply that genetic recombination brings a population closer to linkage equilibrium; if $D = 0$, recombination does nothing, and there is no selection for higher or lower recombination.

Selection, however, can maintain linkage disequilibrium in a population provided that (1) the loci concerned are reasonably close (that is, do not recombine too freely), and (2) there are 'epistatic' fitness interactions between them. 'Epistasis' means that the effect of substituting an allele at one locus depends on what allele is present at the other. If, for example, *AB* and *ab* were of high fitness and *Ab* and *aB* of low fitness, this would be an extreme example of epistasis. Alternatively, one could say that *AB* and *ab* were 'co-adapted' sets of genes, and that *Ab* and *aB* were not. Given such fitness interactions, it is easy to see that the frequency of *AB* and *ab* gametes will tend to be high and of *aB* and *Ab* gametes low (that is, the population will be in linkage disequilibrium), and also that there will be selection for lower recombination, because recombination will tend to produce *Ab* and *aB* gametes. In other words, either there is no selection on recombination, or selection will reduce it. This is what led Turner to ask his question.

Before seeking an answer, I first describe an experiment to measure the strength of selection. In *Drosophila*, it is possible (by using inversions and relying on the fact that there is no recombination in the male) to breed flies whose chromosomes are identical to ones present in adult wild-caught flies, and to compare their viability and fertility with flies whose chromosomes have undergone a single round of recombination since their extraction from adult wild-caught flies. Charlesworth and Charlesworth[6] performed such an experiment, and found a small (and statistically non-significant) reduction in viability, and a larger and statistically significant reduction in fertility. This measure of the 'recombinational load' confirms the theoretical prediction that selection favours a reduction in recombination. Yet recombination is almost universal. Three kinds of explanation have been suggested.

(1) Chiasmata are needed to ensure proper disjunction in meiosis, and genetic recombination is an unselected byproduct. It is hard to believe this. Male Diptera manage an effective meiosis without chiasmata. Even if this were difficult to evolve, localisation of chiasmata at the ends of chromosomes, where they would have little genetic effect, would surely be possible.

(2) Recombination accelerates evolution to meet changing conditions; species which lose or reduce recombination go extinct in competition with those which retain it. The snag with this long-term 'group selection' theory is that whenever people have looked for genetic variance in recombination rate[7-13] or chiasma frequency[14] within a species they have found it. So if there is short-term selection for reduced recombination it will be effective, whatever the long-term consequences for the species. Nevertheless, this type of explanation is assumed in many discussions of the evolution of recombination rates.

(3) There is some short-term selection for higher recombination, because real populations are not in genetic equilibrium in a uniform environment. It is with theories of this third kind that this article is concerned. They are of three kinds, and allow for the fact that the environment is unpredictable, that relatives compete with one another, and that linkage disequilibrium will arise by chance in finite populations.

An unpredictable environment

It is widely assumed that if the environment is unpredictable, so that offspring meet selective forces different from those acting on their parents, then it will pay a parent to produce recombinant gametes. I have shown[2] that this is true only if the environment is unpredictable in a special and rather implausible way. Consider an environment with a number of variable features, A_m or a_m, B_m or b_m and so on (these can be thought of as hot/cold, wet/dry and so on), and a population with alternative alleles A or a, B or b adapting individuals to different features. Then it can be shown that, even with random dispersal of offspring and changing frequencies of the alternative states between generations, any selection on recombination will favour a reduction. In particular, if alleles at two different loci, say A_1 and A_2, adapt an individual to state A_m, and alleles a_1 and a_2 to a_m, then there will be selection for reduced recombination.

Only in the very extreme case of unpredictability, in which the correlations between environmental features—say A_m with B_m and a_m with b_m—change sign between generations will there be selection for increased recombination; that is, only if hot places tend to be dry in one generation and to be wet in the next.

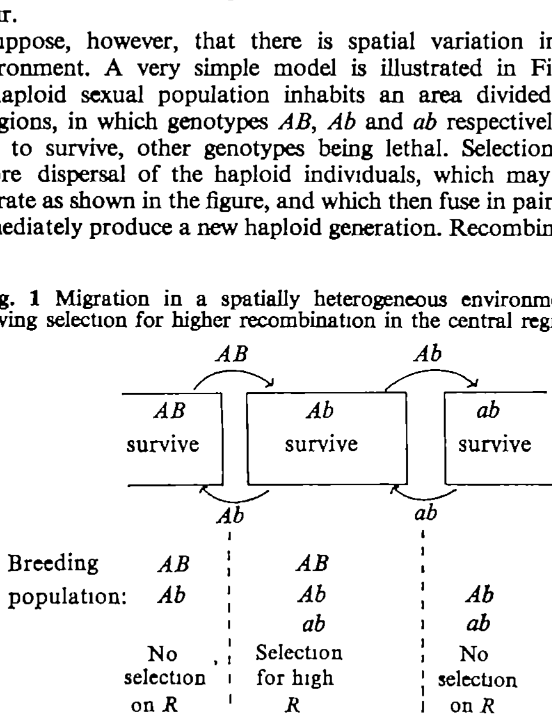
This conclusion may be counter-intuitive. If so, I think it is from anthropomorphism. We argue 'I must not put all my eggs in one basket, because I might lose them all.' But in competition between two types, say H and L for high and low recombination, what matters is not that each individual should have at least one surviving offspring, but whether individuals of type H or L have on average the larger number of surviving offspring. In these circumstances, it pays to put all your eggs in one basket if it is a better-than-average basket.

In this analysis[8], I considered frequency changes for one generation only, for a rather artificial selection regime. A more realistic genetic model was considered by Charlesworth[15], with essentially similar results. He considered a population in an environment which fluctuated either cyclically or stochastically, and found that the allele for higher recombination increased in frequency only in those simulations in which D_m (the value of D which would have been reached at equilibrium if environmental conditions were held constant) changed sign from time to time; this in effect requires that correlations between selectively relevant features should change sign, as in my model. He also found that the periodicity (or autocorrelation) of the environmental change was important.

These models of an unpredictable environment do show that there can be short-term selection for increased recombination. My own judgement of them, however, is that they show that the widespread belief that environmental unpredictability is sufficient to account for recombination is wrong, because the type of unpredictability required is of a kind which may seldom occur.

Suppose, however, that there is spatial variation in the environment. A very simple model is illustrated in Fig. 1. A haploid sexual population inhabits an area divided into 3 regions, in which genotypes AB, Ab and ab respectively are able to survive, other genotypes being lethal. Selection acts before dispersal of the haploid individuals, which may then migrate as shown in the figure, and which then fuse in pairs and immediately produce a new haploid generation. Recombination is irrelevant in the terminal regions. In the central region it is advantageous in the double heterozygotes AB/ab, since it enables them to produce viable Ab offspring.

Fig. 1 Migration in a spatially heterogeneous environment, giving selection for higher recombination in the central region.



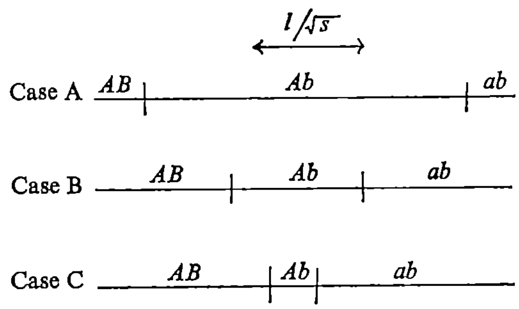


Fig. 2 Relation between the typical migration distance, $l/\sqrt{s}$, and the distance between environmental discontinuities. AB, Ab, and ab are the fittest genotypes in the respective regions.

Slatkin[16] analysed a more realistic model (Fig. 2). He considered a linear habitat with two boundaries, at one of which selection switches from favouring allele A to a, and at the other from B to b. If the boundaries are far apart (case A), two independent clines arise; there is no linkage disequilibrium and no selection on recombination. If they are coincident or close together (case C) there will be linkage disequilibrium either side of the boundaries, and selection for reduced recombination.

If the boundaries are an intermediate distance apart (of the same order as the 'characteristic distance' $l/\sqrt{s}$, where l is the typical distance an individual moves, and s the selective advantage per locus) there will be selection for higher recombination between the boundaries (case B). Hence for a spatially varying environment there can be selection for increased recombination. Unfortunately it is equally easy to think of situations (case C) in which selection favours reduced recombination.

Competition between sibs

Williams[17,18] has pointed out that if sibs compete with one another it will pay a parent to produce a genetically variable family. Computer simulation[19] shows that this can be a powerful force favouring sexual as against asexual reproduction or high as against low recombination. The basic model is shown in Figure 3. To fix ideas, imagine a population of self-incompatible hermaphrodite plants. The environment is divided into 'patches', each large enough to support one adult plant. Each patch has a number of features—5 in the simulations—each of which can be in one of two states, A_m or a_m, B_m or b_m . . . E_m or e_m. In each generation the states of each patch are randomly assigned, the 32 possible types being equally common.

Individuals are diploid, with 2 alleles at each of 5 linked loci, A or a, B or b and so on. Genotypes AA and Aa are equally adapted to A_m, and aa to a_m; the other loci are similarly related to other features. Thus an individual can be adapted to O, 1 . . . . . 5 features of the environment.

There are L patches, and hence L surviving adults. To produce a new generation, a new set of L patches is generated randomly. Each patch receives N seeds from each of R female parents. To produce N seeds, 2 parents are chosen randomly and offspring produced according to the usual laws of genetics. The 5 loci are linearly arranged, and the rate of recombination between them is determined by alleles at a sixth modifier locus.

When RN seeds have been produced in a patch, one survivor is chosen randomly from those best adapted to it. A successful parent, therefore, is one who produces many winners. Since there can be only one winner in each patch, it pays to produce as variable a family as possible. Since recombination increases within-family variability, alleles for high recombination increase in frequency.

Some results of simulating the model are given in Table 1.

Table 1 Selective advantage of recombination

Population size, *L*	Parents per patch, *R*	Offspring per parent, *N*	Total selection intensity, *NR*	Recombination fractions C⁻	Recombination fractions C⁺	Number of generations	Frequency of allele C⁺ Initial	Frequency of allele C⁺ Final	Estimated selective advantage of C⁺/C⁺
200	4	8	32	0.0	0.5	15	0.265	0.462	+0.165
200	5	10	50	0.05	0.5	10	0.262	0.387	+0.181
400	5	10	50	0.05	0.5	6	0.330	0.426	+0.182
400	5	10	50	0.05	0.25	6	0.301	0.388	+0.189
400	5	10	50	0.05	0.25	6	0.305	0.355	+0.115
Locus of C unlinked to fitness loci									
400	5	10	50	0.05	0.5	6	0.316	0.375	+0.127
400	5	10	50	0.05	0.5	6	0.272	0.325	+0.147

There is a substantial advantage for recombination. In contrast to the models discussed in the next section, the advantage does not disappear if the modifier locus is unlinked to the fitness alleles.

Thus by modifying the 'unpredictable environment' model to allow for competition between sibs, one obtains substantial short-term selection for higher recombination. There are, however, two reasons why sib competition cannot by itself explain why the genome does not congeal. First, the dispersal pattern of the species must be such that sibs compete with one another, yet meet environmental conditions different from those in which their parents survived. Second (as in the models discussed in the last section), if alleles at two loci adapt an individual to the same environmental conditions, selection will reduce recombination between them.

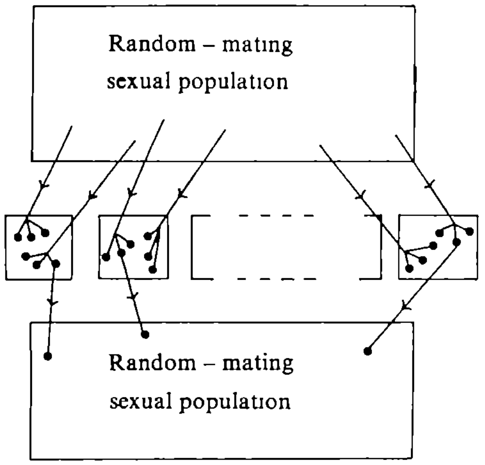
Hitch-hiking and the evolution of finite populations

'Hitch-hiking' is easiest to understand for genes which modify the rate of mutation. Suppose that a mutator gene causes a unique favourable mutation which increases in frequency and becomes fixed. If there is no recombination the mutator gene will also be carried to fixation. This theoretical possibility was discussed by Leigh[20], and Cox & Gibson[21] showed that a gene for a high mutation rate was repeatedly carried to fixation in a non-recombining population of *E. coli*.

Strobeck *et al.*[22] suggest that a similar process may select for alleles for higher recombination. Consider a particular case. A population has a balanced polymorphism for a pair of alleles *A* and *a* (for example, because *Aa* is fitter than *AA* or *aa*). A unique favourable mutation *B* occurs, say in an *AB* gamete. *B* will increase in frequency for a time, but if there is no recombination this increase will be interfered with by selection at the *A* locus. In the absence of *aB* gametes, *B* cannot go to fixation.

Suppose now that there is a pair of alleles C^+ and C^- at a third linked locus, such that recombination between *A* and *B* occurs only in C^+/C^+ genotypes. Sooner or later an aBC^+ gamete will arise by recombination, and will increase in frequency. The allele C^+ hitches a lift from the *aB* gamete it has produced, but only if it can hang on; that is, only if *C* is closely linked to *A* and *B*.

Fig. 3 Dispersal pattern for the sib-competition model, with 3 offspring per parent, and 2 parents contributing to each patch.



Random – mating sexual population
Random – mating sexual population

A simulation is shown in Figure 4. In fact the allele C^+ receives two lifts. The first can be down (case A) or up (case B), according to whether the original *B* mutation occurred in repulsion or coupling with C^+. The second, when an aBC^+ gamete is produced, is always upwards. The average effect is always to increase the allele for higher recombination.

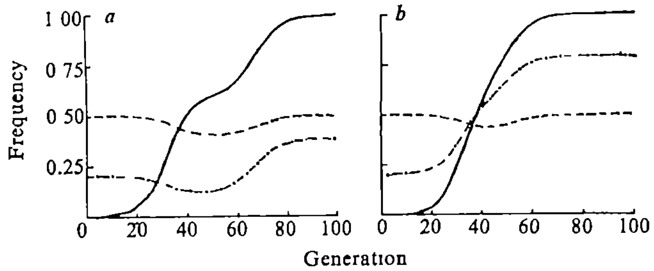


Fig. 4 The hitch-hiking effect on a gene for recombination: *a*, gene frequencies when *B* is initially in coupling with C^-; *b*, gene frequencies when *B* is initially in coupling with C^+. – – –: frequency of A; ——: frequency of B; —·—: frequency of C^+.

The process operates whenever evolutionary changes occur in a population with selectively maintained polymorphisms; to that extent it is universal. But how important is it? Strobeck *et al.*[22] simulated a range of values of selection and recombination rates. The net effect, if any, is always to increase recombination. The main limitation is that the net increase in C^+ is vanishingly small unless, in the absence of C^+, the three loci are closely linked. Hence the process explains why the genome does not congeal completely, but may not account for the high levels of recombination actually observed.

Hitch-hiking is a phenomenon of finite populations. In an infinite population *AB* and *aB* gametes would both arise by mutation. Felsenstein[23] pointed out that models showing a short-term or long-term advantage for sex are usually finite-population models. He suggested that this is because in a finite population linkage disequilibrium will arise by chance (Hill & Robertson[24]). This led Felsenstein & Yukoyama[25] to simulate finite populations initially polymorphic for alleles affecting recombination, in which a succession either of favourable or of unfavourable mutations occurred. They observed selection for higher recombination in these populations. Two favourable genes interfere with one another just as a favourable and heterotic gene interfere. A modifier which can cause recombination between two favourable or two unfavourable alleles may get a lift from the favourable recombinants it has produced.

The remaining problem

Three types of model in which selection for increased recombination occurs have been considered. Models incorporating an unpredictable environment have two drawbacks; they require an extreme and implausible type of unpredictability, and they imply selection for reduced recombination whenever several loci are concerned with the same environmental feature. Models incorporating sib competition overcome the first but not the second of these drawbacks; they introduce an additional requirement for a pattern of dispersal which, while not implausible, is certainly not universal.

Finite-population, hitch-hiking models have the required universality. They have the drawback that there is substantial selection only if the modifier locus is tightly linked to the loci affecting fitness. In effect, such models explain why the genotype does not congeal, but not why recombination is as free as it is. They will be most effective in populations which are continuously adapting to qualitatively new circumstances. Fisher[3], who, characteristically, was the first to hint at a mechanism of this kind, wrote "It is apparent that for this process to have been an effective check upon the constant tendency to increase the intensity of linkage, the stream of favourable mutants must be an abundant one."

New oceanic data on the structure and variability of the Antarctic Circumpolar Current (ACC) in the Drake Passage and its interaction with the atmosphere have revealed a more complex spatial structure than has been seen before. They also show a significant coherence between surface wind and deep current at short periods. These new results will be essential in understanding the role of processes in the polar regions in global climate dynamics.

OCEANIC data have been obtained from two sets of closely spaced density sections and a year-long moored current meter array carried out during two international (U.S., Argentina, Chile, U.S.S.R.) multi-ship operations in the Drake Passage (between South America and the Antarctic Peninsula) in January–March 1975 and January–March 1976. These expeditions (FDRAKE: First Dynamical Response and Kinematic Experiment) are part of the International Southern Ocean Studies (ISOS), a component of the International Decade of Ocean Exploration of the Intergovernmental Oceanographic Commission of UNESCO. The atmospheric data are from an analysis of surface pressure for 1975 provided by the Australian Bureau of Meteorology in Melbourne. The data will be discussed in greater detail in several papers to be published elsewhere[1–4] but we present here a summary of the major results on the structure of the flow field and its response to atmospheric and bottom topography interactions.

The primary purpose of FDRAKE 1975–76 was to begin to establish a 'climatology' of the ACC system in the Drake Passage by the use of monitoring sections of current meter arrays and closely spaced hydrographic measurements. The mooring arrays were deployed and recovered by the current meter group from Oregon State University; and the hydrographic and chemistry work was carried out by groups from Texas A & M University and Oregon State University with technical support from the Scripps Institution of Oceanography. The hydrographic work in 1975 (refs 5–7) and 1976 (refs 8–10) included measurements of temperature, salinity, oxygen, phosphate, silicate, nitrate, and nitrite. When combined, these data provide a sharper picture of water masses and their characteristics in the regions adjacent to the Drake Passage, and they facilitate interpretation of data from the moored arrays. Data from the cruises were combined to give a nearly synoptic picture of the polar front zone from the Drake Passage to the Falkland Plateau and information on a second frontal zone, the Weddell–Scotia confluence. The work on the polar front zone is discussed in detail elsewhere[2,3].

A banded spatial structure is unambiguously revealed by the closely spaced hydrographic measurements[4]. In 1975, the stations occupied by the RV Melville were spaced 50 km apart, and in 1976, the station spacing was 45 km, in contrast to the previous work which had spacings generally greater than 100 km. This increased resolution has revealed vertically coherent bands of isopycnal slope steeper than the average downward slope of isopycnals towards the north, so that the density field has a step-like appearance.

The general characteristics of all the closely spaced sections are similar. These density steps produced cores of high geostrophic

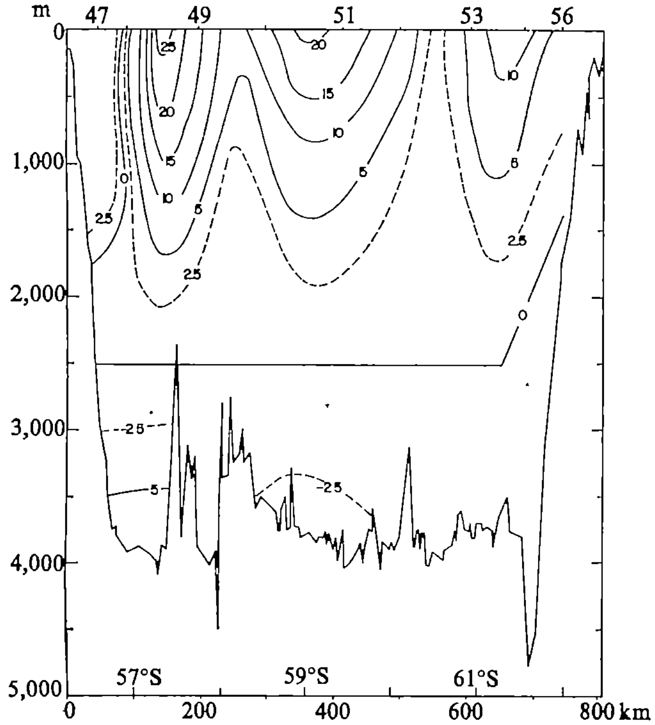

Fig. 1 Geostrophic velocity perpendicular to a line (running 332 °T) across the Drake Passage (positive eastward). The flow is referenced to 2,500 dbar; south of 61 °S, the greatest common sample depth was used as reference for station pairs which did not reach 2,500 dbar

velocity shear. In 1975, the central Passage showed bands of eastward geostrophic speeds ranging from 25–30 cm s^{-1} separated by regions of lower speed (0–5 cm s^{-1}) or slight westward flow (Fig. 1). This core-like structure was observed again in March 1976 when a line of hydrographic stations was made from the RV Thompson approximately 25 km to the east of the current meter array. Three bands of large horizontal density gradient, or cores of relatively strong flow, were observed in this section. The detailed structure of these cores will be discussed elsewhere[4].

Data from cruises of the Ob in 1958 (ref 11), the Washington in 1969 (ref. 12) and the Hudson in 1970 (ref. 13) also provide some evidence for the bands of relatively high horizontal density gradients embedded in the current in Drake Passage. However, the station spacing on these cruises was too large to permit unambiguous description of the detailed current structure. Callahan[14] has observed a similar structure, but with larger scales, in the ACC region south of Australia.

The characteristic scales of the high speed cores is the order of magnitude (20 km) to be expected if the fluid responds (to atmospheric input, bottom topography interaction and/or instabilities) on the scale of the Rossby radius of deformation (defined as $[(g/\rho)(\mathrm{d}\rho/\mathrm{d}z)]^{1/2}H/(2\Omega\ \sin\theta)$ where g is gravity, ρ density, H a characteristic depth (here chosen to be 1,000 m), Ω the Earth's rotation rate, and θ the latitude) averaged over the first 1,000 m. This is the first observation of fluid structure on this scale in this region, although mesoscale structure has been observed and suggested theoretically in other oceans[15]. J. S. Allen and M. McCartney (unpublished data) have shown that stratified, time-dependent flow through Drake Passage topography can lead to a core-like structure, we hope that these new data will stimulate further theoretical work on ocean response to these interactions in the southern ocean.

In February 1975, an array of 42 current meters on 15 moorings was deployed in the Drake Passage: 23 were recovered after three weeks, and 19 were recovered during February 1976, having measured currents over periods from 220 to 350 d.

These long-period records give us a unique data set for this region to define temporal and spatial statistics (previous measurement periods were a maximum of 13 d). To estimate time scales, an autocorrelation function for velocities in the through-passage direction (062 °T) is calculated[1] for the long-term current record nearest 2,700 m. The period of the first zero-crossing of the autocorrelation function, which averaged 14 d, is an estimate of the time-scale of dominant energy containing motions. The period of independence of the records is estimated at 7 d. The 7-d averages of flow in the through-passage direction vary from −2.9 (westward) to +7.6 (eastward) cm s^{-1} over the measurement period of 1 yr Only two of these mean flows are significantly non-zero at a 95% confidence level. Figure 2 shows the variation in the 14-d averaged through-channel flow over the year. A three regime structure is marginally present, reminiscent of the three-core hydrographic data. Note the strong changes on the northern side of the Passage The low frequency variability is strongest on the northern side of the Passage, while the high frequency variability does not seem to change significantly over the width of the Passage

The detailed statistics of this long-term variability of the deep flow will be discussed elsewhere[1]. It is, however, interesting that the observed large variability in the flow at 2,750 m now seems to be one of the main reasons for the large range of transports estimated by various authors[12,13] since in making these estimates short-term averages of deep currents were used to reference the baroclinic transports

To estimate space scales, we note that the Rossby radius relevant to deep flow near the mooring number 10 (59°8′S, 63°4′W) is about 20 km. Thus, it is plausible that correlations of horizontal velocity at distances greater than about 40 km should be small[15] This expectation is borne out by the statistical analysis of the current measurements[1] which show no significant correlations over the record lengths at the mooring spacing of about 75 km. The effect of this observed spatial variability on the total transport is discussed elsewhere[1,4]. Significant coherences between moorings have been found for some events shorter than the record length, but

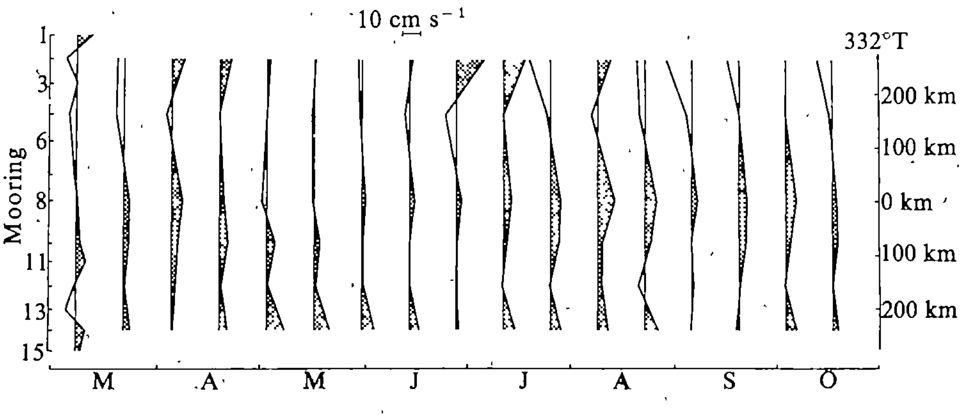

Fig. 2 14-d Averages of flow at 2,500 m from the current meter data, March–October 1975 The coordinate system is oriented in the cross- (332 °T) and through- (062 °T) passage directions. The shaded regions represent positive through-passage flow. During March a larger number of short-term moorings were deployed

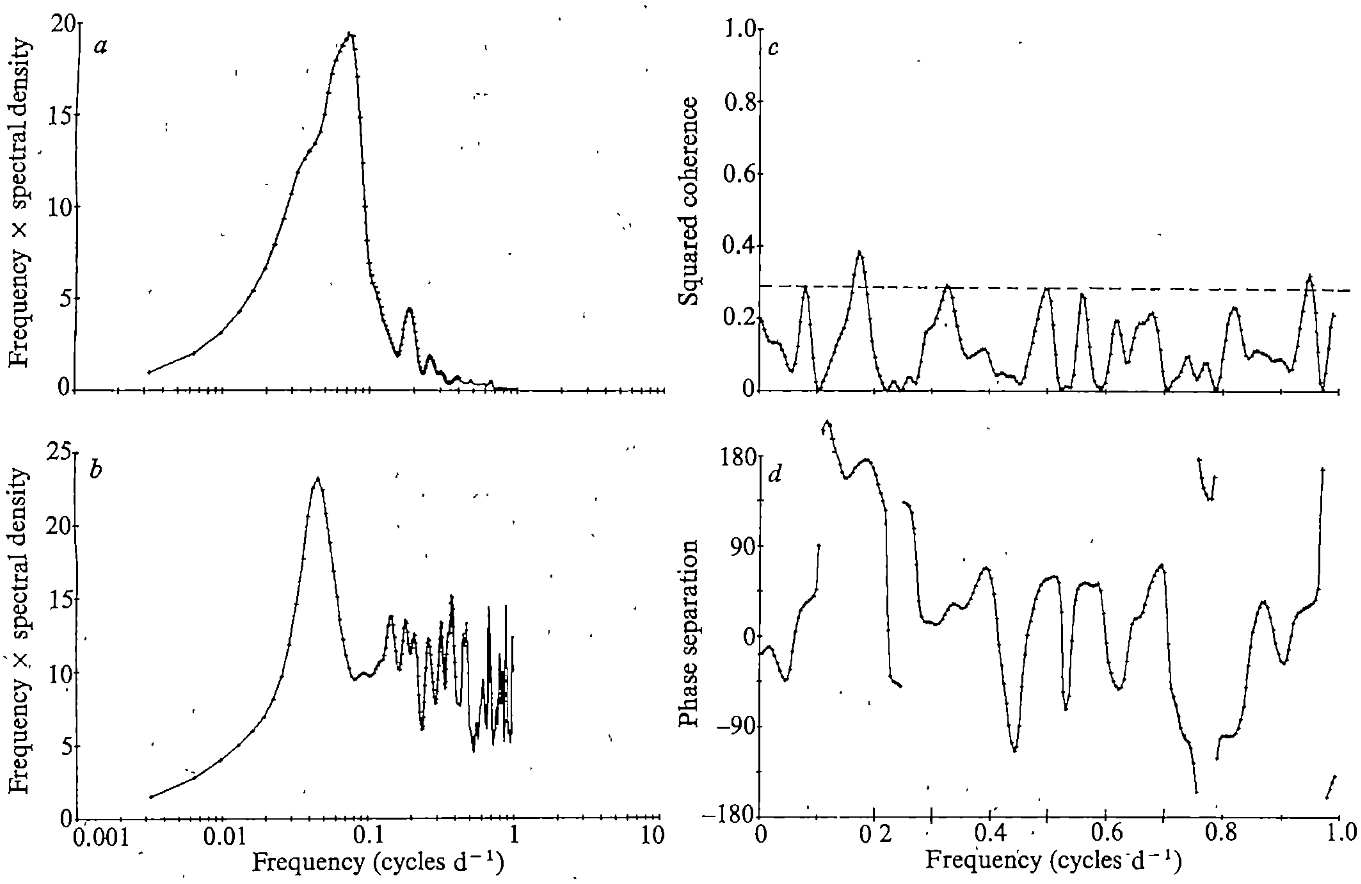

Fig. 3 *a* Spectrum of currents (at mooring 10. 1,519 m, 59°8'S, 63°4'W); *b* spectrum of geostrophic wind (components in the 062 °T, through-passage direction) in the Drake Passage (units are $cm^2\ s^{-2}$ cycles d^{-1} per unit bandwidth (currents); $m^2\ s^{-2}$ cycles d^{-1} per unit bandwidth (wind), *c*, squared coherence of currents and wind, and *d*, phase of currents and wind. Time series are 308 d long, beginning 27 February 1975 See text for discussion of coherence near the 5.5-d scale 95% confidence limits are indicated

these are still preliminary studies. The current meter array in place during 1976 and that designed for 1977 have separations of smaller scales in order to examine velocity correlations more closely.

An analysis of the surface meteorological data has also been carried out for the Drake Passage; 12-h values of pressure and pressure differences have been extracted from the 12 months of 1975 surface pressure analysis. Ten values were used over an area 1,000 × 1,000 km centred on the moored array. Both the pressure spectrum and the pressure difference spectrum, interpreted as geostrophic wind, show a number of peaks in the range of periods from 2 to 14 d, with the bulk of the energy falling at long periods (greater than 14 d). The current meter spectra show peaks near 4 d and 6 d with the bulk of the energy falling between 10 and 100 d (see Fig. 3). Coherence calculations between the through-passage current at 1,019 m and 1,519 m on mooring 10 and the through-passage wind show a significant (at the 95% significance level) peak in the coherence squared at a period of 5.7 d with a stable phase over the peak of about 172°. This coherence is good evidence that atmospheric effects are transmitted deep into the ocean at these high latitudes. It is, of course, possible that this is not a local effect. Since the atmospheric spectra show similar features to the west of the Drake Passage, we may be seeing here an oceanic response which is representative of a larger-scale air–sea interaction in the South Pacific Ocean. The currents are nearly out-of-phase with the local wind, suggesting that a larger-scale interaction may be at work.

The observed coherence between deep ocean currents and wind agrees with calculations by Philander[16] which show that at frequencies less than inertial, and for forcing at large horizontal scales, there can be a response even in the deep water. Philander notes that the large eastward travelling cyclones that dominate the spectrum of surface winds in mid- and high-latitudes should force a response down to the ocean floor in such a weakly stratified region, and that measurements between Iceland and Scotland[17] have shown a correlation between surface atmospheric pressure and deep ocean currents at depths from 300 to 1,000 m. By his calculation, a similar response should be seen in the Drake Passage (the stratification is weak enough and the storm systems are large enough). Therefore, he suggests that the observed variability of deep currents in the Drake Passage is correlated with atmospheric storms; the data tend to bear out this suggestion.

Another question of some interest for Southern Hemisphere air–sea interaction is the existence of semi-annual wave components in the current meter data, which can be compared with the well known semi-annual atmospheric oscillations[18]. Surface ocean data, from sea level and ship drift observations, have shown such a variation[19]. A wave fit to the data from all the FDRAKE moorings shows significant amplitude (defined as greater than twice the standard deviation) at this period at all depths. The magnitudes of the semi-annual component range from 5.7 cm s^{-1} at a depth of 1,019 m to 0.9 to 1.3 cm s^{-1} at a depth of 2,750 m for the through-passage component. The cross-passage component also shows a significant amplitude, with a maximum at the shallower depth. This data set is the first which is long enough to show evidence of such long-term response in the deep water. The possibility of such deep forcing by wind adds a new facet to the complexity of air–sea interaction in high latitudes.

We thank Robert Still of Oregon State University for his contribution to the success of the moored array work. Thanks also go to the Scientific, technical and ship personnel of the RV Conrad, RV Melville, RV Thompson, Ara Islas Orcadas (Argentina) and AGS Yelcho (Chile) who participated in FDRAKE 75–76.

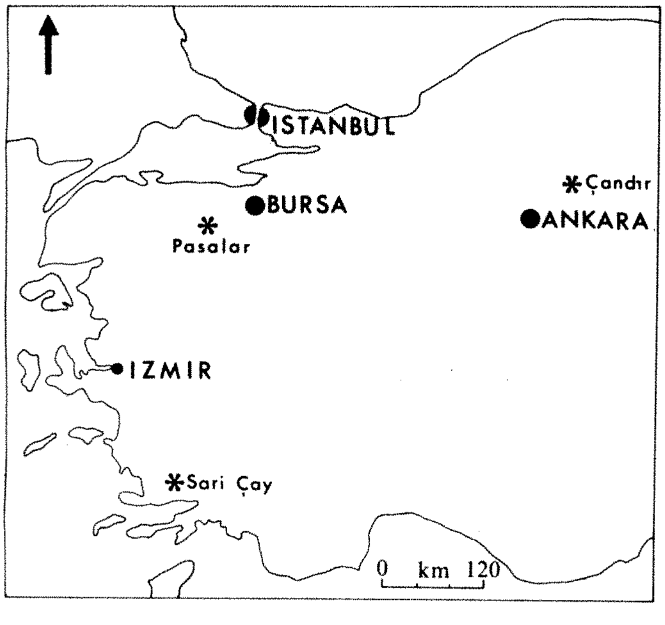
New Miocene locality in Turkey with evidence on the origin of *Ramapithecus* and *Sivapithecus*

Peter Andrews
British Museum (Natural History), Cromwell Road, London SW7, UK
H. Tobien
Johannes-Gutenberg-Universität, Saarstrasse 21, 6500 Mainz

Collections in early Middle Miocene deposits at Pasalar in Turkey have yielded a very rich fauna. Included in this are two hominoid species referred here to Sivapithecus darwini *(Abel) 1902 and* Ramapithecus wickeri *(Leakey) 1962. These are both more primitive morphologically and earlier in time than other species of these genera, and they provide evidence that* Sivapithecus *and* Ramapithecus *are closely related and that their early diversification may have occurred not in Africa but in Eurasia.*

THE mammal-bearing locality at Pasalar, Turkey, is situated 68 km south-west of Bursa, 12 km south-west of Kemalpasa, and about 6.5 km south of the main Bursa–Susurluk road, NW-Anatolia (Fig. 1)[1]. The site was discovered in 1969 during a lignite exploration[2] in the Neogene basins of Anatolia, and is situated near the Southern edge of the Neogene Gönen Basin (west of Bursa)[3]. The lignite survey was inaugurated by the Turkish government, and reconaissance trips and field work were done in 1965–1969 by a group of geologists from the Bundesanstalt für Geologie und Rohstoffe (Hannover, FRG) in collaboration with the Maden Tetkik ve Arama Enstitüsü (MTA, Ankara)[2]. During the field work about 80 fossil vertebrate localities of late Neogene and early Pleistocene age were discovered. Some of these localities were subsequently investigated by a German research team under the leadership of the late Professor Sickenberg in collaboration with Turkish colleagues of the MTA and with the financial support of the Deutsche Forschungsgemeinschaft[2].

Fig. 1 Map of northwestern Anatolia showing the positions of Pasalar and Candir.



Stratigraphy

The fossilferous deposits at Pasalar are exposed in a small road cutting. They are resting directly on Palaeozoic granitic rocks which are clearly exposed on the west side of the road. The fossiliferous sediments consists of 2.2 m of silts and sandstones, often quite coarse, with a considerable thickness of apparently unfossiliferous silts and fine sandstones further up the section to the north and east.

The section exposed on the eastern wall of the roadcut, about 750 m south of the village of Pasalar, is as follows:

0.8 m grey-green silt, unbedded, with many small calcareous concretions, some rare irregularly distributed quartz grains, and many chips of bone of larger mammals and rare isolated teeth of micromammals.
1.0 m whitish to light grey sand, fine grained, unbedded, with frequent lenses of coarser sands and gravels (mainly quartz pebbles up to several centimeters in diameter), unbedded and badly sorted, non calcified. Abundant fossils.
0.4 m grey-green silt, with occasional small red spots, many cm-sized white calcareous nodules, unbedded, unfossiliferous.
Unconformity
Palaeozoic granitic rocks and undifferentiated metamorphosed rocks.

The relatively coarse sediments that make up the fossiliferous series are overlain by a finer grained more strongly bedded succession. Discontinuous beds and lenses of coarse sands, which decrease in frequency up the section, occur throughout. The depositional environment was fluviatile, with rapid sedimentation in high energy conditions in the main fossiliferous bed followed by quieter conditions, but with occasional high energy episodes, later on. This accords well with the location of the sediments, situated as they are on the southern border of the Neogene Gönen Basin at the base of the sedimentary sequence. They probably represent initial molasse-like fill of a tectonic basin near the lower slopes of a mountain range[4].

Prostrepsiceros cf. *rotundicornis*
Bovidae indet.

Fauna

The bulk of the fossil remains come from the sand and gravel layer. Within that bed the fossils are concentrated in the unconsolidated gravels and consist largely of isolated teeth of mammals ranging in size from insectivores to elephants. There are also many fragmentary postcranial elements, and these occur, together with the isolated teeth, in very great local concentrations.

The faunal list (Table 1) for the main fossiliferous bed is provisional except for the carnivores[5], proboscidians[6] and rhinoceroses[7]. The description of the other groups is under preparation, and a preliminary account of the primates is given here. They are referred to two species of *Ramapithecus*[8-10] and *Sivapithecus*[11-13] on the basis of morphological similarities with previously described species.

In the lithostratigraphic subdivision of the late Neogene in Western Anatolia, the Pasalar sequence represents an equivalent of the Middle Miocene Turgut member. More specifically its mammalian fauna can be correlated with the fauna from Prebreza (Yugoslavia)[5], and it is somewhat earlier than the faunas of Bjelometscheskaya (Northern Caucasia) and Sansan (France)[1]. It is also one of the earliest of the Anatolian Miocene *Anchitherium* faunas[1]. In the traditional European timescale Pasalar corresponds with the early Vindobonian[5], slightly older than Sansan. In the biozonation of the Mediterranean Neogene based on mammals it belongs to the NM zone 5 (ref. 14). In the sequence of European continental mammal ages/stages, proposed by the Symposium München 1975, the NM zone 5 is the uppermost member of the Orleanian age/stage[15]. In terms of the marine stratigraphy of the Paratethys and Tethys the Pasalar niveau would probably correspond to the Tharkanian (Eastern Paratethys), Lower Badenian (Central Paratethys) and Upper Langhian (Tethys) respectively. The radiometric age of the Langhian timespan is between 15.03 and 16.27 Myr (ref. 16).

Fossil primates

The collection of primates from Pasalar consists of 100 isolated teeth : 14 of these are broken, allowing measurement of enamel thickness, but the rest are intact and well preserved. They group readily into two size categories, large and small, and on this basis a minimum number of individuals of 20 has been calculated, taking account also of the degree of wear of the teeth and whether they are from the left or right side, 12 for the large category based on 69 specimens, and 8 for the small category based on 31 specimens. Most of these are from the main fossiliferous bed, but three specimens are known from the overlying grey–green silt.

There are 11 incisors and canines in the collection. Five of these are upper central incisors, the large specimens having an expanded lingual pillar, so that they are intermediate in morphology between *Proconsul nyanzae* and *Sivapithecus indicus*, while the small incisors are similar in morphology to *Proconsul* incisors. In size the large specimens are equivalent to the I^1 of *Proconsul major* while the small ones are equivalent to very small *P. nyanzae*. (*Proconsul* here is considered to be a valid genus[10].) The five canines are all from the left side and are very similar to each other both in size and morphology (Fig. 2*d*). They are the same size as *Sivapithecus indicus* canines, and it is assumed that they belong to the large size category.

There are 22 premolars in the Pasalar collection. The P^3 is similar in size to P^4 (Fig. 2*b*) and is not buccally elongated. The P^4 is represented by eight specimens in the large category, all from the left side, and one specimen in the small size category. They are similar in morphology to *Sivapithecus* and *Ramapithecus* except that they are slightly broader relative to length. The P_3 samples are much more distinctive. The crowns are robust and low crowned and they have prominent mesiolingual cingula which end consistently in small-to-large beak-like processes (Fig. 2*d*, *e*). These are not usually seen in *Sivapithecus* species, although the size and degree of robustness of the crown is similar to

Fig. 2 Composite tooth rows of Pasalar primates. *a*, Left and right dp^4 and left M^1–M^2 of *Ramapithecus wickeri*. *b*, Left P^3–M^3 of *Sivapithecus darwini*. *c*, Left dp_4 and M_1–M_3 of *Ramapithecus wickeri*. *d*, Left C–M_3 of *Sivapithecus darwini*. *e*, Right P_3–M_3 of *Sivapithecus darwini*.

BP, Bursa-Pasalar; MTA, Maden Tetkik ve Arama Enstitusü, Ankara. Triangles indicate the type specimens of *Sivapithecus darwini*. The + signs indicate the Siwalik sample of *Sivapithecus* with the means for *S. indicus* and *S. sivalensis* taken from ref. 13 shown enlarged. The very small open circles represent *Ramapithecus punjabicus*. The stars represent small samples of *Dryopithecus laietanus* and *D. fontani*.

that of *Sivapithecus indicus*. The P_4 crowns are much more similar to those of *Proconsul* species, particularly their constricted trigonid regions and the presence of buccal cingula.

There are 18 upper and 32 lower molars from Pasalar. The size ranges in all the teeth are approximately equivalent to the ranges of *Sivapithecus indicus* for the large size category, and *Ramapithecus* species for the small category (Fig. 3). The upper molars are extremely similar in morphology to each other and to the molars of *Sivapithecus indicus*, and are quite unlike the molars of *Proconsul* species (Fig. 2*a*, *b*). This is mainly due to the presence on both of thick crown enamel which results in low rounded cusps, constricted trigon basins, and blurred occlusal ridges. Enamel thickness on the molars varies from 1.7–2.5mm in unworn teeth of the large size category to 1.1–1.5mm on slightly worn teeth of the small size category. The lower molars also have low rounded cusps and constricted talonid basins due to greater enamel thickness, and in this they resemble *Sivapithecus* and *Ramapithecus*, but in general proportions the lower molars are more like those of *Proconsul*. This is partly due to the buccal cingulum, which is prominent (Fig. 2*c*, *e*) and imparts a squared outline to the crown of M_1 and M_2, but also the trigonid is constricted and the M_3 has an elongated talonid narrowing distally. This *Proconsul*-like morphology of the lower molars contrasts with the *Sivapithecus*-like morphology of the upper molars, but there is little reason to doubt that the uppers and lowers at Pasalar are associated. Finally there are four deciduous teeth in the collection from Pasalar (Fig. 2*a*, *c*) all belonging to the small-size category.

Phylogenetic implications of fossil primates

The Pasalar primate sample of hominoid primates has been divided into two size classes (Fig. 3). They are too distinct to be the result of sexual dimorphism within a single species, but apart from that they are very similar to each other morphologically. There are, however, some morphological differences between the two groups, particularly in the I^1 and P_3, and we conclude, therefore, that they represent two different but closely related taxa. Both taxa are broadly intermediate in morphology between early Miocene *Proconsul* species and later Miocene *Sivapithecus* and *Ramapithecus* species, but they must be classified with the latter rather than the former because they share apomorphus (derived) characters with the later species of *Sivapithecus* and *Ramapithecus*, for example the thick enamel on the molars. The characters they share with the early Miocene species, such as molar cingula and narrow trigonids, are either primitive characters retained by both groups or synapomorphies present in all the dryopithecines.

The large species is the same size as *Sivapithecus indicus* from the Siwaliks[12]. But, it differs from *S. indicus* in many respects, particularly in the morphology of the central incisor, third premolar and lower molars, as well as being rather earlier in time. It also differs from *S. sivalensis* in many of the same ways, and most resembles *Sivapithecus darwini* (Abel)[11,12]. This is a poorly represented fossil species known from deposits in the Vienna basin that are about the same age as the Pasalar deposits. The morphology and size of the primate specimens from the two localities are almost identical, and the Pasalar species is therefore referred to *Sivapithecus darwini* until further discoveries, especially of mandibular or maxillary material, make a more detailed assessment possible.

The teeth representing the small species from Pasalar are very similar to those of the mandible recently described from Candir[5], Turkey. This has been referred to *Ramapithecus wickeri*[9] on the basis of mandibular as well as dental morphology. The Candir deposits are similar in age to those of Fort Ternan, which is the type locality of *R. wickeri*, but the Pasalar deposits seem to be a little older, and related to this the Pasalar *Ramapithecus* is slightly more primitive than *R. wickeri* from Fort Ternan and Candir. On present evidence the difference is not considered great enough to justify a new species name for the Pasalar form, so it will be retained in *R. wickeri*.

Stratigraphically the Pasalar deposits are intermediate in age between the early Miocene deposits of East Africa and the later Miocene dryopithecine localities of Europe and Asia[13]. This raises the possibility that the primates from Pasalar, which have also been shown to be intermediate morphologically, may provide a phylogenetic link between early Miocene *Proconsul* of Africa and later Miocene *Sivapithecus* and *Ramapithecus* of Eurasia. In this event, the great degree of similarity exhibited by *S. darwini* and *R. wickeri* from Pasalar, which suggests a closer relationship between *Ramapithecus* and *Sivapithecus* than hitherto recognised[10,13], indicates that there may be represented at Pasalar a very early stage in the origin and radiation of these two genera. This radiation was almost entirely confined to Europe and Asia, with the exception of *R. wickeri* from Fort Ternan (and some doubtfully assigned specimens of *Sivapithecus*), and although the origin of this radiation will probably ultimately be traced to Africa, on present evidence it seems that its initial diversification took place outside of Africa and probably in Central Asia.

A genetic model for sympatric speciation through habitat diversification and seasonal isolation

Catherine A. Tauber & Maurice J. Tauber

Department of Entomology, Cornell University, Ithaca, New York 14853

Based on studies with natural populations, we offer a genetic model for sympatric speciation that could have broad application to polyphagous animals with habitat differences. The model comprises three steps, each of which includes simple genetic changes and plausible selective forces.

ALLOPATRIC speciation as the almost universal, single mode of speciation in bisexual animals has been the subject of lively dispute[1–6]. As an alternative, Maynard Smith[7] proposed a theoretical model for sympatric speciation through disruptive selection in a two-niche situation. The details of this model were subsequently extended, especially for plants[8].

Until now, the most convincing evidence supporting the application of Maynard Smith's model to bisexual animals comes from studies with monophagous insects that form divergent host races[9–12]. In fact, Bush[5,13] suggested that sympatric speciation through disruptive selection is restricted to host specific, phytophagous or parasitic animals. Far more controversial are cases of proposed sympatric speciation through, for example, diversification in habitat association or seasonal distribution[1,3,14–16]. Unlike the cases involving host races[9], there are no step-by-step genetic models for this type of speciation mainly because there is a lack of information on the inheritance of ecophysiological response patterns controlling habitat preference and seasonality in animals.

Work with two green lacewings, *Chrysopa carnea* Stephens and *Chrysopa downesi* Banks (Insecta: Neuroptera), has shown that single allele differences at two loci result in gross alterations in photoperiodic responses controlling seasonal timing of reproduction[17]. Also, allelic changes at three loci can explain the sympatric speciation of *C. downesi* from a *C. carnea*-like ancestor[18]. Based on these and other analyses of genetic differences between *C. carnea* and *C. downesi*, we present a genetic model for sympatric speciation through habitat diversification and seasonal isolation. This model involves three steps—each of which includes simple genetic changes and plausible forces of disruptive selection. We propose that our specific model has broad application to animals that differ from sympatric relatives in both habitat association and in reproductive season. We also show that Maynard Smith's general model[7] for sympatric speciation is applicable to bisexual, polyphagous, as well as monophagous, animals.

Reproductive barriers

C. carnea and *C. downesi* readily hybridise in the laboratory and produce fully viable and fertile F_1 and F_2, as well as backcross offspring; in these conditions, there are no behavioural or post-mating reproductive barriers between the two species. But, no hybrids are found in nature and the two species are kept clearly separate through the action of two types of premating reproductive barriers—differences in their habitats and differences in their seasonal periods of reproduction[19].

Reproductively active *C. carnea* adults, which are light green, occur in grasslands and meadows, in cultivated fields, occasionally on deciduous trees, and rarely on conifers. In these habitats, the adult coloration provides camouflage, presumably against vertebrate predators. At the end of summer, as the adults enter reproductive diapause, they move to the senescent foliage or leaf litter of deciduous trees where they overwinter[20,21]. This movement is accompanied by a colour change (from light green to reddish brown) that maintains the camouflage in the overwintering site. In contrast, *C. downesi* adults do not change colour and the species is restricted to coniferous trees, where the very dark green colour of the adults provides camouflage. *C. carnea's* occasional occurrence on coniferous trees indicates a slight overlap in habitat with *C. downesi*; but, in general, the two species are spatially separated.

Adults of both species undergo diapause, during which reproductive behaviour, ovarian development, and sperm transfer are suppressed. *C. carnea* enters diapause at the end of August and it remains in diapause until mid-January or February[22]. Postdiapause mating takes place before the vernal equinox, and the first postdiapause generation adults emerge about June, after which two more summer generations are produced. Therefore, mating by *C. carnea* occurs during late winter and also during summer[23]. In contrast, *C. downesi* has only one generation per year, and the adults, on emergence in June, enter a diapause that persists through summer, autumn and winter[18]. This species ends its diapause around the time of the vernal equinox[24]; mating takes place in early spring. Therefore, *C. downesi* is reproductively inactive during *C. carnea's* entire reproductive period.

The seasonal cycles of *C. carnea* and *C. downesi* are primarily controlled by photoperiod[25]. Their asynchrony largely results from *C. downesi's* short day–long day requirements for diapause prevention, and for diapause termination. These short day–long day requirements evolved from photoperiodic response patterns that *C. carnea* and *C. downesi* share, that is, responsiveness to a change in daylength and responsiveness to the actual duration of daylight (or darkness) per 24-h period[17,25,26].

The species-specific responses are under genetic control, and a pair of alleles at each of two loci regulate the expression of the *C. carnea* versus the *C. downesi* response pattern[17]. Homozygous recessive alleles at both loci result in the short day–long day requirements that underlie the univoltinism of *C. downesi*.

The preoviposition period of non-diapausing *C. downesi* is considerably longer than that of non-diapausing *C. carnea* (Table 1). The average preoviposition period of F_1 and F_2 hybrids and backcross progeny, reared in diapause-averting conditions is also consistently longer than that of *C. carnea*, and it is usually intermediate to those of *C. carnea* and *C. downesi* (Table 1). The range in the preoviposition period in the F_2 intercross progeny (see ranges on Table 1) shows very little overlap with the *C. carnea* range. This suggests that even one *C. downesi* allele at one of the two diapause-controlling loci can lengthen the preoviposition period. In addition, modifier genes could also be involved.

Genetics of adult coloration

To determine the mode of inheritance of the dark green adult coloration of *C. downesi*, we made reciprocal P_1 and F_1 crosses between *C. carnea* and *C. downesi*. We scored the colour of the F_1 and F_2 offspring using three broad categories: 'true *carnea*', 'true *downesi*', and 'intermediate'. We also divided the 'intermediate' category into three subcategories: '*carnea*-like', 'true intermediate', and '*downesi*-like'.

All the F_1 offspring of the two reciprocal crosses of *C. carnea* × *C. downesi* fell into the 'intermediate' category; they ranged from '*carnea*-like' to '*downesi*-like' intermediates. In the F_2 progeny, coloration occurred in the three broad categories in ratios that do not differ from those expected for the segregation of a single pair of autosomal alleles—one recessive, one semidominant (Table 2). The 'intermediate' individuals again varied from '*carnea*-like' to '*downesi*-like'. Therefore, we conclude that *C. downesi* coloration is due primarily to a single, semidominant autosomal allele (which we designate as *G*); expressivity of the dark green colour is apparently modified by polygenes.

Sympatric speciation of *C. downesi*

On the basis of the distributional and biological[25] characteristics of *C. carnea* and *C. downesi*, we conclude that *C. downesi* is the more recently evolved. The multivoltine *C. carnea* occurs over most of the Holarctic Region, whereas the univoltine *C. downesi* is restricted to the more northern regions of North America. We know of no place where *C. downesi* is present without *C. carnea*, nor are we aware of evidence that the two species were ever geographically isolated.

Table 1 Preoviposition period of conspecific and interspecific crosses between *C. carnea* and *C. downesi*

$\chi^2 = 1.25$; $P = 0.5$–0.8.

We propose that *C. downesi* diverged sympatrically from an ancestral population of *C. carnea*, and that it did so through the establishment of a stable polymorphism for habitat utilisation and the subsequent development of reproductive barriers between the morphs in the two habitats.

The evolution of a stable polymorphism is based on the ancestral population's occurrence in two types of habitats: the meadow–field–deciduous tree habitat to which the population was well adapted, and the coniferous habitat, to which it was less well adapted. We propose that in the *C. downesi* ancestor the mutation of gene *g* to gene *G* (the autosomal, semidominant allele that produces the dark green cryptic coloration of *C. downesi* adults) provided a selective advantage for individuals carrying gene *G* in the coniferous habitat. The selective force that favoured gene *G* in this habitat was probably the action of vertebrate and invertebrate predators. This proposal is supported by our observations (in preparation) that conifer-inhabiting species of Chrysopidae are either cryptically (dark green) coloured (as in *Chrysopa harrisii* Banks and *C. downesi*) or they produce a malodourous secretion (as in *Meleoma emuncta* Banks) that is offensive to vertebrate and invertebrate predators[27]. Therefore, in the coniferous habitat, the dark green colour of the *C. downesi* adult provided homozygous *GG* and heterozygous *Gg* adults with a selective advantage over the pale green (*gg*) form. Conversely, the light green, homozygous *gg* form retained its selective advantage over *G* individuals in the original habitat. The two homozygous forms, *GG* and *gg*, were therefore virtually restricted to separate habitats; whereas heterozygous *Gg* individuals, with their intermediate coloration, were at a competitive disadvantage in both habitats. Thus the population was subjected to disruptive selection. This selection presumably led to the establishment of a stable polymorphism involving light and dark green colour forms—each in its own habitat. Genetically-controlled preferential mating was not necessary to this step in the speciation process because disruptive selection maintained the balanced polymorphism even if both colour forms remained within a single random-mating population. But the frequency of pairings between *GG* and *gg* was probably low because of the restriction of adults of each colour form to their separate habitats.

The inheritance of *C. downesi*'s dark green colour is not unlike that proposed for early melanic forms of *Biston betularia* (L.). Kettlewell[28] deduced that the original *B. betularia* melanic form resulted from a single, semi-dominant allele which later became dominant. In contrast to the polymorphism in the ancestral *C. downesi*–*C. carnea* population, the balanced polymorphism in *B. betularia* is based on heterozygote superiority, a situation that would allow the evolution of dominance modifiers[29] and the maintenance of interbreeding between morphs. We propose colour change rather than alteration in habitat choice as the initial step leading to speciation of *C. downesi* because it allows the establishment of a stable, habitat polymorphism based on a single gene system. In contrast, alteration of habitat choice would have been more complex because at least two gene differences would be needed to establish a stable polymorphism.

Once a stable polymorphism was established, two selective forces probably favoured the evolution of the univoltinism of *C. downesi*, the characteristic that serves as the primary reproductive barrier between the forms. First, univoltinism increased the adaptation of the coniferous form to its habitat, and second, it served to reduce or eliminate the wasteful production of the less fit heterozygotes. In contrast, the multivoltinism of the original form continued to be favoured in the original habitat. During summer, the number of conifer-inhabiting predators, such as other green lacewings (*C. harrisii*[30] and *M. emuncta*) and other arthropods (hemerobiids, syrphids, hemipterans, spiders, mites), increases, whereas available prey decreases (C.A.T. and M.J.T., in preparation). Therefore competition among conifer-inhabiting predators seems to be very intense during summer and we conclude that in the *C. downesi* ancestral form selection favoured a univoltine seasonal cycle that included reproduction in early spring, larval occurrence in mid to late spring, and reproductive diapause during summer, autumn and winter. This reproductive cycle would not have been advantageous to the original, non-coniferous form because in its habitat, prey were available throughout spring and summer.

Single allele differences at two loci underlie the seasonal asynchrony of *C. carnea* and *C. downesi*[17]. Thus, the mutation of the recessive '*downesi*' alleles at these two loci and their replacement of the dominant '*carnea*' alleles in the dark green coniferous form, resulted in the evolution of the seasonal reproductive barrier between *C. carnea* and *C. downesi*. We represent the mutation of the two diapause-controlling alleles from '*carnea*' to '*downesi*' as $D_1 \rightarrow d_1$ and $D_2 \rightarrow d_2$.

The evolution of the unicyclic *C. downesi* seasonal cycle probably took place in two separate phases: (1) the addition of the aestival diapause and (2) the extension of the autumnal diapause through winter. The summer diapause conceivably reduced the incidence of interform pairings by approximately two-thirds, because two of *C. carnea's* three annual generations reproduce during summer. The extension of the autumnal diapause through winter probably eliminated the interbreeding of overwintering populations by delaying sexual maturation in *C. downesi* in relation to *C. carnea*. We propose that each of the two diapause-controlling loci regulates one of these two differences in the seasonal cycles. Recessive '*downesi*' alleles (d_1d_1) at one locus probably result in diapause induction in long-day conditions, and this locus functions in the expression of the aestival diapause. Recessive '*downesi*' alleles (d_2d_2) at the second locus probably act in maintaining diapause until after short days are experienced and they therefore serve to prolong diapause through winter. We have no evidence showing which of the alleles (d_1 or d_2) first mutated and/or replaced its dominant counterpart in the coniferous form. The '*downesi*' alleles were strongly selected against in the original non-coniferous form because of their negative effect on the reproduction rate Even one d_1 or d_2 allele at one of the diapause-controlling loci lengthens the preoviposition period (Fig. 1), which, in the original habitat would be clearly deleterious. Thus, strong disruptive selection resulted in the replacement of the dominant '*carnea*' alleles by the recessive '*downesi*' alleles in the coniferous form. As a result. the seasonal cycles of the two forms became asynchronous, interbreeding between the forms ceased, and *C. downesi* was established as a species.

Subsequent to or concurrent with the evolution of reproductive isolation, at least two types of changes increased *C. downesi's* fitness in the coniferous habitat: (1) the evolution of habitat selection and (2) modification of the thermal requirements for development. Those *C. downesi* individuals that recognise and remain in the coniferous habitat would have a higher chance of leaving offspring than those that choose the non-coniferous habitat or that choose their habitat at random. This behaviour is probably genetically controlled, but the numbers and types of genes involved are unknown.

The second change in *C. downesi* was the alteration in the lower thermal threshold (t) for growth and development. *C. downesi* from Ithaca has a slightly (~2 °C) but significantly higher t value than *C. carnea* from the same area[18]. In nature, this slightly higher threshold acts as a precise fine-tuner of *C. downesi* univoltinism.

Genetic model

Using our data from *C. downesi*, we present a genetic model for sympatric speciation through habitat diversification and seasonal isolation by non host-specific animals. Our model begins with a hypothetical ancestral species that is well-adapted to several habitats. This species is neither restricted to a particular host, nor confined to a particular plant association. Occasionally it occurs in a secondary habitat to which it is less well adapted. Also, it is multivoltine and reproduction encompasses a broad period of the annual cycle.

Step 1, the establishment of a stable polymorphism in a two-habitat situation, is similar to the first step in Maynard Smith's general model[7] for sympatric speciation. It begins with the mutation of gene a to gene A, a semi-dominant allele that confers a selective advantage on homozygous AA individuals in the secondary habitat. Disruptive selection acts in favour of aa individuals in the original habitat, in favour of AA individuals in the secondary habitat, and against Aa individuals in both habitats. Thus, a balanced polymorphism involving the A and a alleles that adapt individuals to differing habitats is established even if both morphs remain in a single, random-mating population. Assortative mating, if it does occur in the two forms because of their habitat differences, would probably not have a genetic basis.

Step 2, the evolution of seasonal isolation, involves the non-simultaneous mutation and selection of diapause-controlling alleles that restrict the seasonal period of reproduction in the new form. In our model, recessive alleles (b and c) at two unlinked loci act individually or in combination to produce a restricted (or unicyclic) seasonal cycle. Selection pressure for the b and c alleles in the new morph comes from two sources: (1) by synchronising reproduction with favourable seasonal conditions in the new habitat, the alleles increase the adaptation of the new AA form, and (2) by reducing the incidence of interform pairings they reduce the production of the less fit Aa heterozygotes. Because the original, multivoltine seasonal cycle is well adapted to the original habitat, selection acts to keep the recessive b and c alleles out of the aa population; this selection is enhanced if the diapause-controlling alleles in the heterozygous condition also produce unfavourable effects. Disruptive selection such as this leads to the establishment of two seasonally-isolated populations—the original $aaBBCC$ in the original habitat and the new $AAbbcc$ in the new habitat. With the completion of this process, the new species is established.

Step 3 in our model comprises changes that increase the fitness of the newly-formed species. For example, selection favours individuals of the new species that recognise and choose the 'correct' habitat. Therefore, genetic changes associated with the physiology and behaviour of habitat selection are likely to occur. Selection also favours changes that fine-tune the seasonal isolation of the two species and that increase the new species' synchrony with favourable seasonal conditions in its habitat. The physiological characteristics involved in these changes are usually under polygenic control[26,31,32].

We thank Bruce Wallace, Cornell University, and John T. Doyen, University of California, Berkeley, for reading the manuscript.

Variable mid-latitude X-ray source 3U0042+32

THE faint high latitude X-ray sources are a mixed population of galactic and extragalactic objects. Identified extragalactic X-ray sources include clusters of galaxies, Seyfert and other active galaxies, quasars, and nearby normal galaxies[1,2]. Identified galactic sources with $|b^{II}| > 20^\circ$ include several X-ray binaries, two in globular clusters —M15 (ref. 1) and NGC1851 (ref. 3)—the hot white dwarf HZ43 (ref. 4), the dwarf binary AM Her (ref. 5) and the flare star UV Ceti (ref. 6). The high-latitude sources generally lie in fields of low obscuration and density of objects so that the prospects for their identification with optical or other counterparts are relatively good, given position measurements of moderate accuracy. We report here a precise celestial location (1′ error radius) for one such X-ray source, 3U0042+32 (ref. 1), that is situated at mid-galactic latitude ($b^{II} \sim -30^\circ$). A study of the error box for this source indicates that it may be a distant galactic binary system similar to Her X-1.

In early February 1977, Ricketts and Cooke[7] reported a flareup in the intensity of a source in the region of 3U0042+32. Their observations, carried out with the Ariel V X-ray satellite, showed that this source, which had been below the level of detectability during a total of 50 d of scanning since November 1974, was variable up to 25 Uhuru counts per s during 3–6 February, 1977 and up to 50 Uhuru counts per s during 14–17 February. Variability in 3U0042+32 had previously been reported during the interval 1971–73 (refs 8 and 9).

Following receipt of a private communication of the Ariel-5 observation, the SAS-3 X-ray observatory was oriented to bring the flaring source within the field of its rotation modulation collimators. At the time, the location of the Sun was such as to restrict the period of useful star tracker data to only 20 min per orbit. Nevertheless, sufficient exposure was obtained during 25–26 February, 1977 to enable us to make position measurements with the data from both the 2.3 and 4.5 arc minute collimators and in two separate energy channels.

The characteristics and use of the rotation modulation collimator detectors on SAS-3 have been described previously by Doxsey *et al.*[10] and Schnopper *et al.*[11].

Table 1 Rotating modulation collimator positions* for 3U0042+32

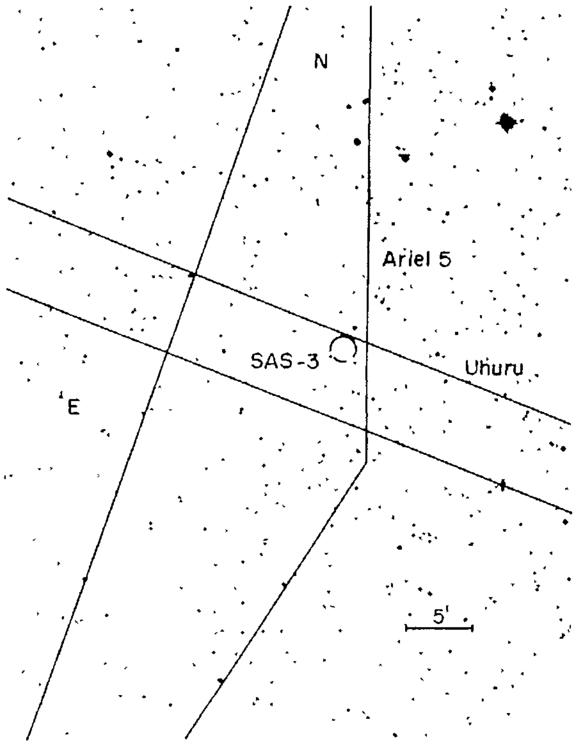
Data set 2	α = 00h42m09s δ = 32° 44′ 57″	α = 00h42m09s δ = 32° 44′ 43″
Average	α = 00h 42m 08.5s δ = 32° 44′ 53″	

*Epoch 1950.0

Table 1 summarises the results on the position derived from the two independent modulation collimators. For each collimator the data were subdivided into two parts, representing the first and second halves of the observation. The mean position obtained from the combined results is α = 00 h 42 m 08.5 s; δ = 32° 44′ 53″ (epoch 1950.0) with an error circle of 1′ radius (90% confidence).

Figure 1 is an enlargement of the red Palomar Sky Survey print of this region with the SAS-3 error circle superposed on it. Also shown are the error box of 3U0042+32, the intensity of which is listed as 7.0±0.5 counts per s in the Uhuru catalogue[1], and the error box of the flaring source studied with Ariel V. It is likely that all three observations pertain to the same object, and that it lies inside the SAS-3 error circle. Within or very near this circle, there are seven stellar images above the plate limit and with visual magnitude ≲ 15.5. Harris *et al.*[12] have studied this region in detail at both radio and optical wavelengths. They point out only one weak radio source in the

Fig. 1 Enlargement of the red Palomar Sky Survey print of the region near 3U0042+32 (copyright National Geographic Society). The solid lines represent portions of the Uhuru (3U) and Ariel V error boxes[1,7] for this source. The 1 min radius error circle is derived from data obtained with the rotation modulation collimators on SAS-3 (see text).



vicinity of the SAS-3 error box (~ 2.2′ from the centre). Bahcall *et al.*[13] have also searched for the optical counterpart to this source, but without success.

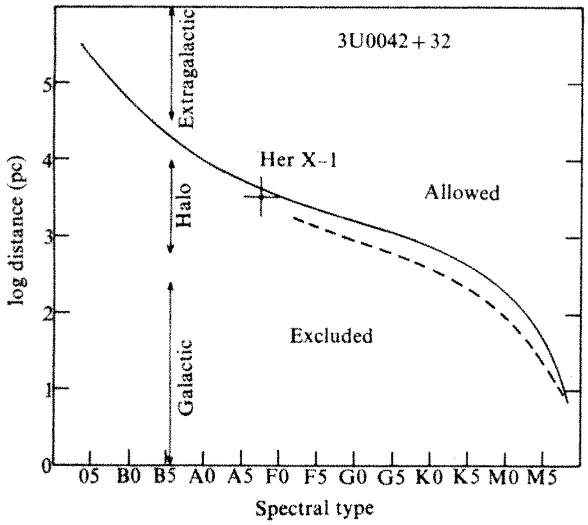
At the conclusion of the position measurement SAS-3 was switched to the fast timing mode (8 ms resolution; see ref. 14). The source was studied for regular pulsations in the range 16 ms to 20 s. Analysis of data from three satellite orbits yielded an upper limit to pulsing in this range of ~ 15% of the steady source intensity (~ 35 Uhuru counts per s). During 27.3–27.7 February, 1977, the *y*-axis detectors[15] were pointed at the source in order to search for possible longer period pulsations. These results also proved negative with a pulsing limit of ~ 7% set in the range of 1 s to ~ 500 s.

Spectral data in the energy range 1–19 keV were also obtained with the *y*-axis detectors. The energy spectrum is nearly flat out to ~ 10 keV ($\alpha = 0.0 \pm 0.4$), with a characteristic cutoff energy of $\leqslant$ 1.5 keV. At higher energies the spectrum falls off rapidly with increasing energy.

The peak X-ray flux from this source (50 Uhuru counts per s) is ~ 50 times greater than the optical flux from the brightest object ($m_v \approx 15.5$) in the error circle at the time of the Palomar exposure. The timescale of its variations, according to the Ariel V observations, is of the order of days. Its spectrum resembles that of hard X-ray binaries which derive their power from accretion on to a compact star. We believe that the most likely explanation of this flaring source is that it is a neutron star in a close binary system with a companion that undergoes occasional episodes of mass transfer due to eruption or orbital eccentricity (compare ref. 16).

The limit on the optical magnitude of the stellar companion ($m_v \gtrsim 15.5$) places significant constraints on the distance to 3U0042+32 for various assumed spectral types. These distance constraints are summarised in Fig. 2. For each spectral type the absolute visual magnitudes of a main sequence dwarf and subdwarf star[17] were used; any larger stars would require still larger distances. A companion star earlier than spectral type B5 would probably lie beyond the galactic halo. Stars of very early type are likely to be excluded, in any case, because a comparison of the Palomar red and blue plates indicates that none of the stellar images within the SAS-3 error circle exhibits a large blue excess. Only stars of type ~ K5 or later would be consistent with a location within ~ 200 pc of the galactic plane. A distant late A or early F star, similar to HZ Her[18,19] (= Her X-1) would be consistent with all presently available data on 3U0042+32.

Fig. 2 Minimuma llowed distance to 3U0042+32 against assumed spectral type of an hypothetical binary companion star. The solid and dashed curves are derived from the magnitude of the brightest star in the SAS-3 error circle ($m_v \sim 15.5$) and the absolute visual magnitudes of main sequence dwarf and subdwarf stars[17], respectively. Interstellar extinction was assumed to be negligible. Parameter values for Her X-1 (refs 18 and 19) are shown for reference.



The possibility that the source is extragalactic is remote. The peak X-ray intensity of the source is equal to that of the Perseus Cluster[1] yet there is no active galaxy or known quasar in the error circle[12,13]. The short timescale of the X-ray variations implies that the source must be 'compact' (that is, $\lesssim 10^{16}$ cm) as opposed to, for example, an extensive region of hot intracluster gas. One might then expect the spectrum of such an extragalactic object to be highly absorbed, by analogy with other compact extragalactic sources (for example, Cen A, 3C273, and NG4151; ref. 20). On this latter point, our limited spectral data may not be decisively negative. Nevertheless, if the source is extragalactic, it must be of a kind not previously observed.

Supernovae and molecular clouds

In a study of the CO distribution in the Galaxy, Bash and Peters[1] concluded that there is an upper limit of 30 Myr to the age of stellar systems which contain CO. Younger systems, launched by the impulse of the density wave show abundant CO emission. Systems which have existed for longer than 30 Myr display no CO emission. Based on their initial observations, Bash and Peters predicted that there would be a correlation between the presence of CO emission and the turnoff in open clusters. Observations by Green confirm this prediction[2] showing CO emission in at least 24 of 28 clusters with turnoff earlier than spectral type BO and no evidence of CO emission in 35 of 38 clusters with turnoff later than BO. We suggest that there is a critical mass M_{crit} such that for $M > M_{\mathrm{crit}}$ stars do not evolve to an explosive phase and hence the surrounding molecular cloud is substantially unaffected by the evolving stars. As the system ages, the most massive star with $M < M_{\mathrm{crit}}$ finally evolves to an explosive endpoint and the resulting supernova dissipates the dense molecular cloud. From the cluster observations we identify $M_{\mathrm{crit}} \sim 15\text{–}20 M_{\odot}$, the mass of a BO star (ref. 3 and E. Green, private communication), although there is some uncertainty in luminosity class.

An alternative is that one is merely seeing an excitation phenomenon, that stars with $M > M_{\text{crit}}$ are necessary to excite the CO molecules and those with $M < M_{\text{crit}}$ are unable to excite. The basic argument against this possibility is that the disappearance of CO emission seems to be correlated with the disappearance of HII regions as well[2]. HII and CO regions have very different excitation characteristics and, hence it seems unlikely that they could both be made to vanish simultaneously by altering a single source of excitation.

A crucial point to the present argument is that a supernova be able to disrupt the molecular cloud. Molecular clouds have mass up to $\sim 10^5 M_\odot$ and density $\sim 10^4$ cm^{-3}. Such large clouds have a gravitational binding energy of $\sim 2\times10^{50}$ erg and an atomic/molecular binding energy $\sim 3\times10^{51}$ erg. Thus, a healthy supernova should be able to disrupt a cloud as massive as this if all its energy is utilised for this purpose. Mouschovias[4] argues, however, that a supernova in such a cloud will pass from the adiabatic Sedov phase to the isothermal, or snowplow, phase long before the shock produced by the supernova reaches the surface of the cloud. If this were the case only the momentum at the onset of the isothermal phase, not the energy of the supernova, would be available. The initial momentum of a typical supernova, $(2M_{\text{SN}}E_{\text{SN}})^{1/2}$, is capable of giving an outward velocity of $v \sim 3.2$ km s^{-1} $((M_{\text{SN}}/10M_\odot)E_{51})^{1/2}M_{\text{cl},4}{}^{-1}$. The escape velocity is $v_{\text{es}} \sim 4.5$ km s^{-1} $(M_{\text{cl},4}{}^{1/3}\, n_4{}^{1/6})$. Thus, a $10^4\ M_\odot$ cloud can be disrupted by a supernova of $\sim 20\ M_\odot$, roughly the mass we are considering.

Molecular clouds, like stars, follow a fairly steeply decreasing mass function. While the details are not fully agreed on, one can argue that a typical cloud probably contains of order $10^4 M_\odot$; that the $10^5 M_\odot$ clouds are observationally striking, but not representative. In particular, $10^4 M_\odot$ is probably a more typical mass for the molecular clouds surrounding the young open clusters with which we are especially concerned. Thus we conclude that supernovae are the likely cause of disruption of most molecular clouds, even if only their momentum, not their full energy is utilised.

For a $10^4 M_\odot$ cloud with uniform density of 10^4 cm^{-3} the radius (R) is 2.2 pc, the dissociation energy is $\sim 3\times10^{50}$ erg and the binding energy $\sim 4\times10^{48}$ erg. A supernova of $10M_\odot$ and 10^{51} erg will sweep up its own mass entering the Sedov phase at $R \sim 0.2$ pc and $t \sim 30$ yr. This adiabatic phase will end at ~ 0.5 pc and ~ 300 yr when the radiation cooling time drops below the expansion timescale. The rapid leakage of radiation will begin at temperature, $T \sim 1\times10^7$ K for these high densities and be further enhanced at $T \sim 10^6$ K when recombination radiation from heavy ions becomes very strong. An HII region will then race ahead of the original shock front dissociating the cloud. This will lead to a loss of thermal energy and eventually the ionisation energy as the cloud expands and recombines. For a $10^5 M_\odot$ cloud the HII region is probably unable to totally dissociate the cloud. On recombination, the Lyman α flux will be re-radiated from grains as a burst of 10 μm radiation which will escape from the cloud.

Thus while the details are different because of the dense cloud, the evolution of the explosion may be qualitatively similar to the standard picture[5] and we conclude that Mouschovias' arguments concerning the energetics are basically correct. A more careful treatment would incorporate possible density gradients in the cloud. A decreasing density outward, as is observed in many clouds, might serve to prolong the Sedov phase. A step function from low to high density due to a pre-existing H II region would lead to reflected shocks and perhaps an elimination of the already rather brief Sedov phase. These details are presently under consideration in a program which will lead to detailed numerical calculations.

In the simplest picture, the longest lived very bright phase, and hence the one most likely to be observed, may be the Sedov phase. There is an appreciable flux of radiation in this phase, primarily thermal bremsstrahlung, even though it is not sufficient to effect the shock dynamics. This flux of soft X rays will probably be absorbed on grains, raising them to several hundred K and again will be seen in the 10 μm range. The estimated flux is $\sim 5\times10^6 L_\odot$ for a time of about 100 yr. If supernovae occur in our Galaxy with a mean time interval $\lesssim 40$ yr then the present number of events could be $\gtrsim 3$ if they each last ~ 100 yr. Kwan and Scoville[6] have suggested that the Becklin–Neugebauer object may be the site of an explosion.

We have suggested in this note that there exists an upper limit to the mass of stars which explode, ~ 15–$20M_\odot$. This upper limit might exist because of differences in internal structure at the state just before iron core collapse in the final stages of evolution. This possibility leads to the suggestion that stars earlier than BO do not explode because they collapse to make black holes, a notion which is consistent with a suggestion made previously by Wheeler and Shields[7]. Alternatively, these massive stars are known to lose mass and the possibility exists that their mass is reduced to that of a BO before significant evolution from the main sequence can occur (T. Mazurek, personal communication). In this case, the changes in the internal structure, if any, are unclear.

In either case, if this conjecture about an upper mass limit to supernovae proves to be true, quantitative, but perhaps not qualitative, changes might have to be made in notions of nucleosynthesis. Stars from, say, $10M_\odot$ to $20M_\odot$ would still be available as sites of explosive nucleosynthesis and, because of the steep mass function, these are most of the stars which would contribute anyway.

Another important ramification of this suggestion is that star formation would cease with the supernova explosion and the dissolution of the cloud. This picture thus accounts very naturally for the observed inefficiency of star formation in molecular clouds.

We thank J. Scalo and T. Mazurek for useful conversations, and E. Green for permission to quote her results before publication. This research was supported in part by NSF.

Molecular images by electron-wave holography

IMAGES of electron clouds in gas-phase atoms have been photographed[1,2] at a resolution limit of 0.1 Å through a two-stage holographic microscope based on Gabor's principle of image reconstruction[3]. Information encoded on to holograms with electron radiation in the first stage was transformed into a portrayal of electron density in the second stage with the aid of an optical laser. Suitable pictures of gas-phase molecules could not be obtained because of signal-to-noise problems. These problems have now been overcome to a considerable extent and we report here the reconstruction of spherically averaged molecular images displaying light atoms in the vicinity of heavy atoms. Bond lengths can easily be measured with a ruler.

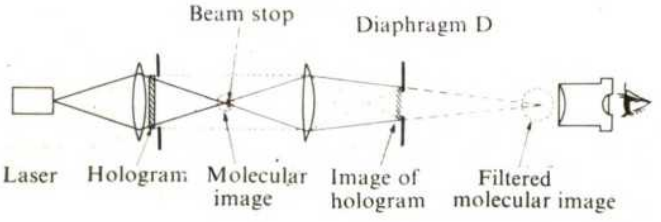
To make holograms yielding high resolving power, it is necessary to produce a broad reference wave that can be mixed coherently with waves emanating from the object under scrutiny. Stringent mechanical stability is also essential. Optical path length differences between the reference beam (source to detector) and object waves (source to object to detector) must not vary during recording by more than a fraction of a wavelength. To achieve these requirements in optical holography, great care must be taken. To achieve them with electron holography, where wavelengths are only one 1/100,000 as long, would be virtually impossible unless the reference beam diffuser were locked internally in the molecular system to be viewed. In atomic holography this was accomplished very naturally for electron cloud objects by scattering the incident wave from the atomic nuclei associated with the electron clouds. In this study of molecules a heavy atom in each molecule served to scatter a strong reference beam. In both cases, then, each particle in the sample to be investigated carries around its own reference wave diffuser, as it were, and produces its own hologram. Holograms from all particles in the sample fall on top of each other. Therefore, the reconstructed images also all fall on top of each other. Instead of seeing individual atoms or molecules we see the average of an ensemble. If all members are identical the images are not degraded. Because our molecular objects are in the vapour phase to reduce extraneous scattering, they have chaotic orientations. Accordingly, we see only the spherical average. This might seem disappointing, but it should be noted that any individual, free molecule in any given quantum state is inescapably diffuse in orientation, and spherically delocalised in the ground quantum state.

For our first molecular investigation we chose AsF_5, an example where five light 'object' atoms (fluorine) are packed with D_{3h} symmetry around a central heavy atom (arsenic). What we should expect to see and do in fact see in the reconstructed image is a spherical shell of atomic fluorines. The radius of this shell corresponds to the mean As–F bond length.

For the first stage of our holographic microscope we used the apparatus previously used for atoms[2], but we reduced the numerical aperture twofold, to $f/2.3$. Resolving power was sacrificed to record with maximum faithfulness the strongest holographic interference fringes. Holograms were recorded on Process plates by scattering 40-kV electrons ($\lambda = 0.06$ Å) from a fine jet of AsF_5 vapour at 20 torr and filtering the electrons through an r^3 rotating sector. This filter is deliberately weaker than the 'Rutherford filter'[2] adopted for monatomic samples to bring out the detail of the light atoms more strongly. Once obtained, the holograms were reduced 18-fold by rephotographing on Kodak 120-02 holographic plates.

Rendering the light atoms visible in the presence of the heavy central atom required a new design for the second, reconstruction stage of the microscope. As before, the desired image is a component of the Fraunhofer diffraction pattern of the hologram. But the holographic fringes corresponding to the As–F bonds are comparatively subtle, and the reconstructed image of fluorine atoms lies very close to the intense 'undiffracted' zero-order beam transmitted by the hologram. (The radius of the molecular image occurs at about the tenth ring of the Airy diffraction pattern produced by the holographic aperture. The beam stop illustrated in Fig. 1 screens through the third Airy ring.) If left at its natural level, this zero-order beam overwhelms the desired image. In principle, the most efficient way of getting rid of the unwanted beam without distorting the molecular image would be to cancel it with another, properly modulated, beam in a Mach–Zehnder interferometer[2]. In practice, it proved much simpler and adequately effective to use a technique suggested by Professor Emmett Leith, namely to remove the zero-order beam differentially by the 'spatial domain filter'[4] illustrated in Fig. 1. An internal calibration of the magnification afforded by the second stage of the microscope could be made easily by measuring the interference spots produced by a 100 line per inch Ronchi grating placed over the hologram.

Fig. 1 Schematic drawing of optical reconstruction stage of holographic microscope. The unwanted beam passing undiffracted through the holographic fringes is largely screened out by the beam stop; most of the remainder is skimmed off by diaphragm D which passes the image-forming rays.



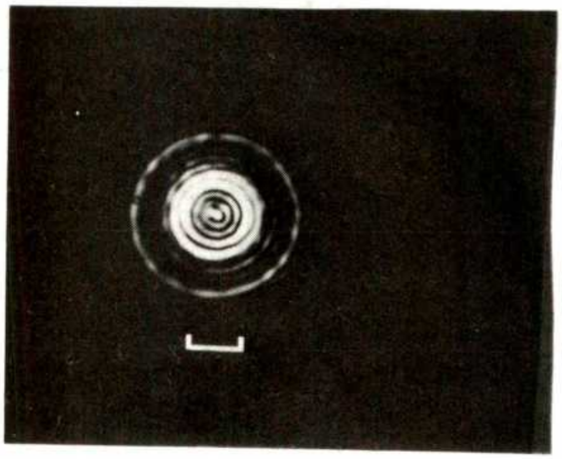


Fig. 2 Holographic image of rotational average of AsF_5 molecules at 70 million power; spherical shell of fluorine atom density plainly visible at 1.6 Å radius. Scale bar 1 Å.

A reproduction of an image of the rotationally averaged AsF_5 molecule at an Abbe resolution limit of 0.2 Å is shown in Fig. 2. Because of the curvature of the spherical shell of fluorines, the maximum density of the projected image lies a few hundredths of an angstrom unit inside the actual mean bond length of 1.68 Å (ref. 5). In principle it would be possible to deconvolute the projected density in Fig. 2 and determine the amplitude of vibration of the As–F bonds from the breadth of the fluorine shell, but this has not yet been done. Since the computed[2] depth of focus of our microscope at the numerical aperture used is about 4 Å and, hence, is appreciably greater than the As–F distance, the three-dimensional aspect of the spherical image is largely lost. As is the case in conventional holography there are 'extraneous contributions' to the image arising from incoherent scattering and from the square of the object amplitude. In heavy exposures the latter contributions show up as shells revealing the $F\cdots F$ non-bonded distance occurring at $\sqrt{2}\, r_{AsF}$, and vestiges of the non-bonded distance at about $\sqrt{3}\, r_{AsF}$. Indeed, given a molecule without a single dominant heavy atom, the laser reconstruction would yield series of concentric shells the profile of which would be closely related to the radial distribution function of internuclear distances in the molecule.

For many years electron diffraction patterns have been measured with microdensitometers sensitive to changes in absorbance of a few parts per ten thousand. Molecular structures have then been deduced by computer analysis of diffracted intensities. In our technique, a much more direct display of structural information is provided immediately by the optical Fourier spectrum of the electron hologram. Although the new technique is not yet competitive in accuracy with the well established scattering techniques, it may find a useful role. Whether analogous techniques can be worked out to study oriented molecules is a challenging problem for the future.

Formation of silver mirror by photolysis of thin films of high molecular weight silver compounds

SILVER salts of carboxylic acids such as formic acid, acetic acid and oxalic acid[1] became coloured in light. Similarly, suspensions of silver polyalkylacrylates produce various coloured colloidal solutions of silver in light[2]. These phenomena show that silver carboxylates are easily photolysed to separate silver. We have investigated the photolyses of silver salts of certain high molecular carboxylic acids such as polyacrylic acid, polymethacrylic acid, poly-L-glutamic acid[3], alginic acid[4], pectic acid[5], carboxymethylcellulose and cellulose acetate phthalate, and we report that the smooth films of these silver salts form a silver mirror arising from photolytic silver on their surfaces. This method of producing a thin silver film on the polymer film may be of technical interest because of the optical and electrical properties of the irradiated film.

Thin films of high molecular weight silver carboxylates (about 4 μm thick) were prepared in the following way. The aqueous solutions of the sodium salts of about 0.5—1% (1 ml) were coated on 20-cm^2 glass plates and dried in the air, then the plates were immersed in silver nitrate solution of 0.1 M for 1 h and washed with water to eliminate sodium nitrate and excess silver nitrate contained in the films, and dried again in the air. For preparation of films of silver salts with smooth surfaces it was essential that the aqueous solutions of sodium salts were dried sufficiently to form the films of sodium salts on the glass plates. This technique thoroughly converted the films of soluble sodium salts into films of slightly soluble silver salts by a rapid ion exchange reaction between sodium ions and silver ions in the films. Thus, the amorphous films of silver salts are prepared on the glass plate, and, if necessary, can be easily peeled from the plate.

The films of all silver salts are colourless and transparent, and show a broad absorption band between 200 nm and 300 nm, which is associated with the charge transfer from carboxylate ions to silver ions. On irradiating with ultraviolet rays (200–300 nm), the films, at first, became brown coloured ($\lambda_{max} = 425$—460 nm) due to the formation of photolytic colloidal silver particles in the films. When irradiation was continued, however, the irradiated surfaces of the films gradually assumed metallic lustre and finally changed into clean silver mirrors. Because of the formation of silver mirrors, the surfaces of the sufficiently irradiated films had very high electric conductivities, which were about 10^9 times as high as those of the original films.

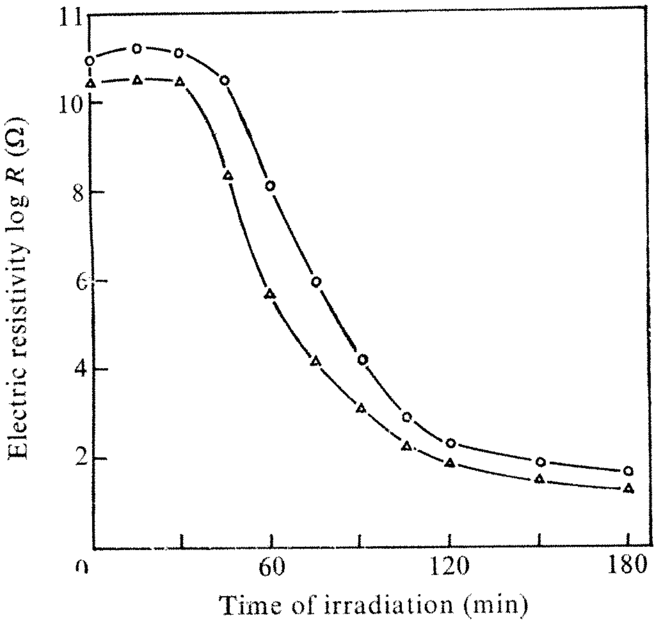

Fig. 1 Plot of log resistivity of the irradiated surface against time of irradiation for silver polyacrylate (○) and silver carboxymethylcellulose (△). The films, about 8μm thick, were exposed to ultraviolet rays from a sterilisation lamp at a distance of 3 cm in air of relative humidity 80% at 20 °C. The electric resistivity (measured in ohm) is that of the irradiated film surface of 1 cm^2. In the electrical resistance measurements, two silver plates (1 × 1 cm) were pressed on to the irradiated surface, at 1 cm apart, with a constant force. Since the photolytic silver existed predominantly on the irradiated surface and a little in the interior of the polymer film, the resistances between the irradiated surface and the rear surface, and of the rear surface scarcely changed with irradiation.

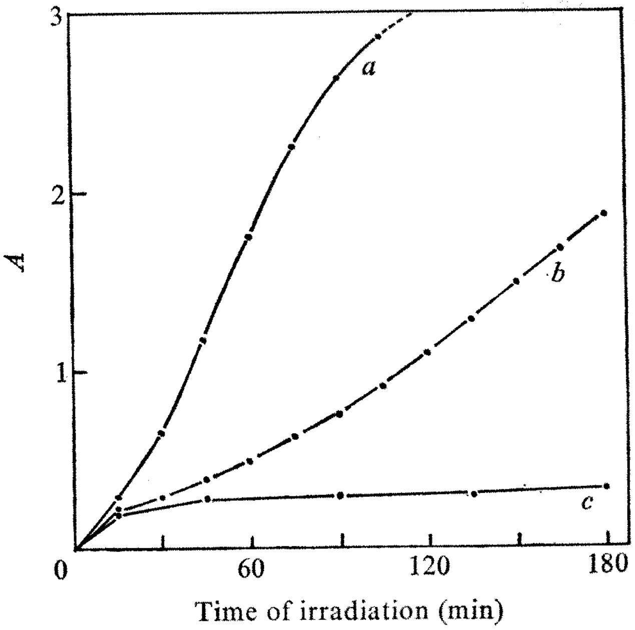

Fig. 2 Effect of water on the separation of silver for carboxymethylcellulose. The films were exposed in various humidities at 20 °C. The absorbance (*A*) was measured with a photographic densitometer. Chemical analysis confirmed that the optical density was proportional to the amount of the photolytic silver in the film. Humidities were, line *a*, 80%; *b*, 59%; *c*, 0%.

Figure 1 shows a plot of log resistivity of the irradiated surface of 1 cm^2 against time of irradiation for silver polyacrylate and silver carboxymethylcellulose. Similar results were obtained for the other silver salts in suitable conditions of irradiation. Since it is clear that the photolytic product which gives high electric conductivity on the surface is metallic silver, it is suggested that silver atoms produced by irradiation aggregate to form the colloidal silver particles near the irradiated surface and finally form a thin layer of metallic silver on the surface[6,7].

Water has a very important role in these photolyses. When irradiation was carried out in a dry box, the separation of silver occurred very poorly even on the prolonged irradiation (Fig. 2), and hence the surface of the film did not exhibit the metallic lustre. To form a silver mirror and increase the electric conductivity on the surface, it is necessary to irradiate the film under an atmosphere of the high relative humidity. It is clear that the water content in the film is closely related to the relative humidity in which it is placed. It seems likely, therefore, that the effect of water results from the action of water as a plasticiser, which facilitates the segmental motion of the polymer and restrains the recombination of the primary products, that is, silver atoms and acyloxyl radicals.

Particulate transport through the mesosphere and stratosphere

THE 'aerosol layers' frequently observed at about 50 km altitude may be due to downward transport from above of particulates, possibly of extraterrestrial origin. This transport would be more efficient at higher altitudes (the mesosphere) than lower altitudes (the stratosphere) thus causing the layering seen in the stratopause region. The flux of particulates through the stratosphere provides a potential scavenging mechanism for pollutants and a source of condensation nucleii to the troposphere. Electric field variations, probably induced from above, can modulate this flux, providing a possible coupling mechanism between geomagnetic activity and terrestrial weather. The particulate distribution is also affected by the general circulation and atmospheric dynamics. The density of particulates is much greater than generally recognised, indicating that their role in chemical and thermal processes should be reassessed.

Noctilucent clouds provide visible evidence of the occasional presence of particulate matter in the high latitude summer mesopause region, but there is also evidence for the continual presence at many latitudes of a high density of very small (<10-nm) aerosol particles in the mesosphere and stratosphere. This evidence includes unexpectedly low and variable ion mobility and conductivity observations (refs 1–6) and ionospheric data such as the normally low density of electrons in the mesopause region[4] and the very rapid loss of electrons during solar eclipse totality[7]. Features of the 'winter anomaly' in ionospheric radio wave absorption, such as the large variability[4] and solar zenith angle dependence[4] of electron density, can be explained by the absence of these particulates on 'anomalous' days.

Optical measurements, using a variety of techniques (Lidar, rocket and satellite scattering measurements at various wavelengths), have indicated 'aerosol layers', frequently in the vicinity of 50 km (ref. 8 contains references to earlier observations). This layering in the stratopause region may be explained by the more effective downwards transport in the mesosphere than the stratosphere of particulate matter, which may be of cosmic origin, possibly coated with ice or water[4]. Gravitational settling of 10-nm particles is less than 10^{-1} m s^{-1} at 80 km, decreasing rapidly at lower altitudes[9]. The dominant diffusion process in the stratosphere and mesosphere is 'eddy diffusion' and the applicable diffusion coefficient is much higher in the mesosphere than the stratosphere, which could produce layering due to 'piling up' in the transition region, the stratopause. The expected eddy diffusion coefficient for the mesosphere[10] yields characteristic downward velocities of order 10^{-2} m s^{-1}, implying a trans-mesospheric transit time of order 30 d. A more rapid process might involve the vertical electric field, which is generally expected to be downward in the upper atmosphere[11]. To provide a net downward transport there must be an excess of positively- over negatively-charged aerosol particles (or a differential mobility). An excess of positively-charged particles would be expected since free electrons form in this region due to detachment (or emission) from negative ions. We need not rely on speculation on this point, however, since Widdel *et al.*[2], using a parachute-borne Gerdien condenser, observed positive ions in the mesosphere with mobilities an order of magnitude less than that of the small positive ions, but did not observe the corresponding low mobility negative ions, indicating that negative particulates did not form, or, more likely, were of very short lifetime due to electron detachment. A consensus of the properties of the particulates in the mesosphere[4] would indicate a density of 10^9–10^{10} m^{-3} of less than 10 nm diameter and a mass of several thousand AMU. Recent measurements of the vertical electric field indicate a field of the order 1 V m^{-1} in the stratosphere, with some intensification in the mesosphere[12]. Assuming a 1-Vm^{-1} field and mobilities for the particulate ions as for the lower mobility group seen by Widdel *et al.*[2], of 1 m^2 V^{-1} s^{-1} at 70 km (10^{-1} at 60) yields velocities of the order of 1 m s^{-1} at 70 km (10^{-1} at 60). Since at least 10% of the available aerosol particles can be expected to be charged (deducible from refs 2, 4, 13), this will provide a transport mechanism at least comparable with eddy diffusion if the electric field measurements are correct.

Recent measurements by Hirono *et al.*[14], using both Lidar and direct electrical measurements on balloon-sondes, indicate a population of 'Aitken' particles in the stratosphere having similar densities ($\sim 5\times10^9$ m^{-3}) to those deduced above for the mesosphere, with a relatively constant density (to a factor of 2) from the tropopause up to 30 km. The eddy diffusion coefficient is much smaller in the stratosphere[15] and the trans-stratospheric transport by this mechanism would be expected to take years. The density of particulates would imply a downward flux of the order of 10^6 m^{-2} s^{-1}. The corresponding electric field transport mechanism is hindered in this region by much lower mobilities (inversely proportional to air density), and is dependent for net transport on a differential density or mobility effect between positively and negatively charged particulates, as before. It would be expected that there might be some differential density effect due to detachment of electrons, as in the mesosphere. Assuming a reduced (STP) mobility of 3×10^{-5} m^2 V^{-1} s^{-1} (ref. 2), the downward velocity would be 3×10^{-2} m s^{-1} at 18 km for a 1 V m^{-1} electrical field, and would be constant above this for the usual assumption that the electric field decreases exponentially with altitude in the stratosphere, consistent with the observation of a relatively uniform particulate density[14]. For a 10% net differential density of positive over negative particulates the downward flux would be of the order of 1.5×10^7 m^{-2} s^{-1} and trans-stratospheric transit would take about 10^2 d. Disturbances of the field, such as have been observed in connection with geomagnetic activity (ref. 16 and R. Mühleisen, personal communication) could modulate or interrupt the flow of condensation nucleii into the troposphere. This is the sort of mechanism which has been suggested to explain possible connections between solar and geomagnetic activity and weather[17,18].

The distribution of particulates would of course also be modified by atmospheric dynamics and the general circulation. One scenario for the 'winter anomaly' in radio wave absorption in the mesosphere would involve the depletion of particulates in sub-auroral regions by an enhanced or reversed vertical electric field, with these regions then being transported by high-velocity equatorward winds. The early winter downdraft at mid-latitudes[19] would be expected to move particulates into the troposphere. A wave-like structure in conductivity observed at a low-latitude site[5] can be explained by a wave-induced bunching of particulates.

The presence of such a high density of particulates in generally downward flow throughout the mesosphere and stratosphere shows that their role in chemical and thermal processes should be evaluated, but this remains uncertain without knowledge of their structure and composition. For example, their effectiveness in scavenging could be greatly enhanced if they are water coated.

It may be that the 'fair weather' electric field expected at the tropopause could be perturbed using high d.c. voltages on high electrodes or antennae, possibly using tethered balloons. Less than 10^6 V on an electrode 1 km above its image would produce an electric field sufficient to double or cancel the expected tropopause electric field (1–10 V m^{-1}) at any latitude. This suggests a means of testing for an interaction between the vertical electric field and atmospheric processes with Lidar or sonde measurements.

Novel method for direct analysis of hydrocarbons in crime investigation and air pollution studies

MODERN methods for sampling of organic vapours in air pollution studies avoid the problems caused by the condensation of water vapour, by collection at ambient temperature on charcoal[1], porous polymers[2–5] or support-bonded phases[5]. The tenacity of adsorption renders the sample difficult to remove and indirect methods such as liquid extraction[1,5] or thermal desorption[2–4] are necessary to produce a sample for gas chromatographic (GC) or GC–mass spectrometric analysis. We describe here an analytical technique based on the Curie point pyrolysis system[6] which overcomes these problems by using ferromagnetic wires coated with a thin layer of highly active charcoal. These are simply suspended in the atmosphere under test for 1–2 h at room temperature, placed in the Curie point apparatus and then inductively heated in the normal manner. Thus the sample is rapidly introduced into the GC for direct analysis. The fact that the total amount of each hydrocarbon present is not adsorbed by this method is outweighed by the advantages of direct sample introduction, which offers distinct advantages to the forensic scientist in the investigation of a suspected arson. The technique could also find quantitative application in air pollution studies.

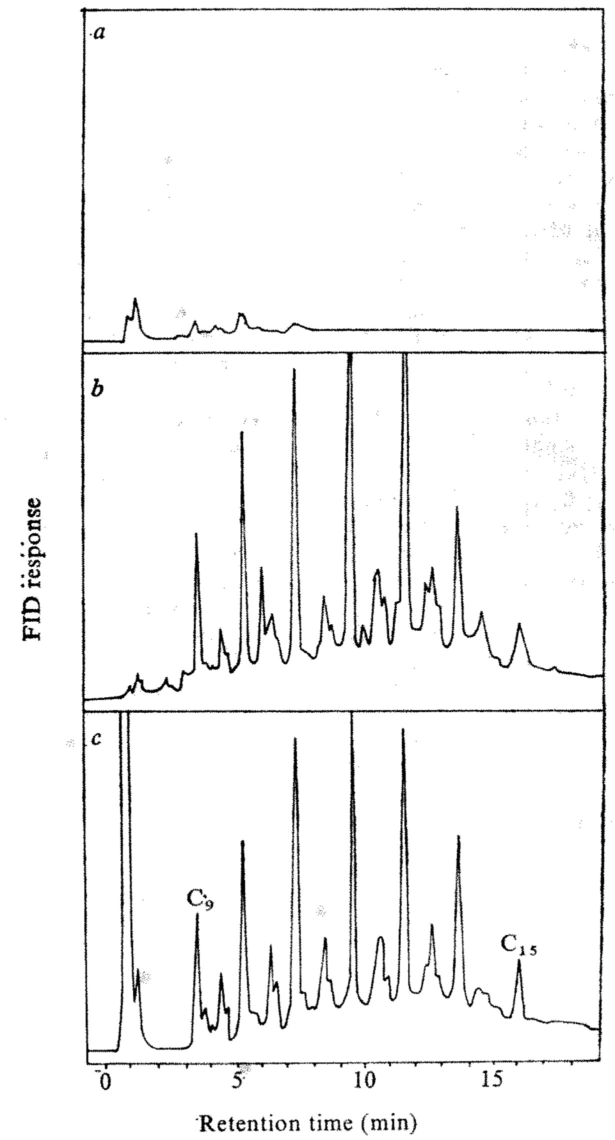

Fig. 1 Gas chromatograms obtained from *a*, 1-ml aliquot taken with heated syringe from a 180-ml glass bottle sealed with nylon film, containing 5μl paraffin and heated to 110 °C; *b*, induction heating for 10 s in the Curie point apparatus of an adsorption wire after 1.5 h immersion in an identical headspace to (*a*), at 22 °C, the chromatogram being obtained at the same attenuator settings as above; *c*, solution injection of the same paraffin sample for reference. Gas chromatography was carried out on a Pye 104 instrument fitted with flame ionisation detectors (FIDs) using 10-foot × $\frac{1}{4}$-inch columns of 15% carbowax 20M on Chromosorb W. A flow rate of 60 ml per min of nitrogen was maintained and the column programmed from 70–180 °C at 8 °C per min. Adsorption wires were prepared by bonding finely divided (passed 240 mesh) highly active carbon (Norit SX1, Hopkin and Williams) to nickel (358 °C Curie point) wires with a high temperature inert adhesive (Cement Binder LQ/S6, Fortafix Ltd). The dried wires were conditioned by several 10-s inductive heating periods in a Pye Curie point apparatus connected directly to the GC column in the normal manner. Wires are ready to use when no further peaks are observed on the GC trace with a subsequent induction heating period. After removal from the apparatus and exposure of an adsorption wire to the vapours under examination, it is returned to the apparatus. The wire is inductively heated for 10 s and the column temperature programming started. At the end of the GC run the wire can be reconditioned for reuse by further repeat inductive heating periods as above. Although 358 °C Curie point wires were chosen initially to avoid pyrolysing the adsorbed material, limited use of 610 and 770 °C Curie point wires suggests that this is not a problem with the hydrocarbon mixtures examined. It is advisable to store conditioned wires over freshly-activated charcoal.

In forensic examination of fire debris for accelerant residues, quantitation has little relevance, the main objectives being to identify the type of accelerant, and where required compare it with a control sample. Current methods rely on the relatively high vapour pressure of hydrocarbons to separate them from the debris. Headspace analysis[7], by direct injection of vapour aliquots taken from a heated nylon bag containing the debris, can often indicate the type of accelerant used. Limitations are imposed on this method by the decrease in vapour pressure of the hydrocarbon species with increasing molecular weight. Thus the less volatile accelerants give poor headspace chromatograms and depletion of the more volatile constituents during a fire creates further difficulties in the identification of the original accelerant. Other techniques involve thermal desorption of the residues followed by cold trapping and are lengthy procedures; the condensate still requiring further processing before analysis. Adsorption traps (J. B. F. Lloyd, personal communication), while improving the procedure again do not provide direct sample introduction. The carbon adsorption wire technique is eminently suited to arson investigation, as it retains the simplicity of headspace analysis whilst producing a much more representative chromatogram, especially for the less volatile material present in the sample.

Figure 1 shows comparisons obtained from identically prepared paraffin vapour samples using hot headspace analysis (Fig. 1*a*) and using an adsorption wire at room temperature (Fig. 1*b*). These comparisons are made at the same instrument attenuation in order to demonstrate the concentrative effect of the wire. The results show that to obtain a response for *n*-decane equivalent to that obtained by the wire 21 ml of hot headspace would be required. Less volatile species show further improvement; for *n*-hendecane and *n*-dodecane, 55 and 200 ml respectively of headspace would be required. Comparison of the wire chromatogram with that of the liquid sample (Fig. 1*c*) demonstrates the wire's ability to adsorb the entire range of components present in a paraffin sample producing a chromatogram closely resembling the original material. Although the adsorption wire chromatogram shows slight differences in fine structure from the liquid paraffin sample, extremely accurate reproduction occurs in the case of petrol samples at the less volatile end. This may be due to slight preferential adsorption of the aromatic species by the carbon, and presents no problems for paraffin samples providing any samples for comparison are also examined by the adsorption wire method.

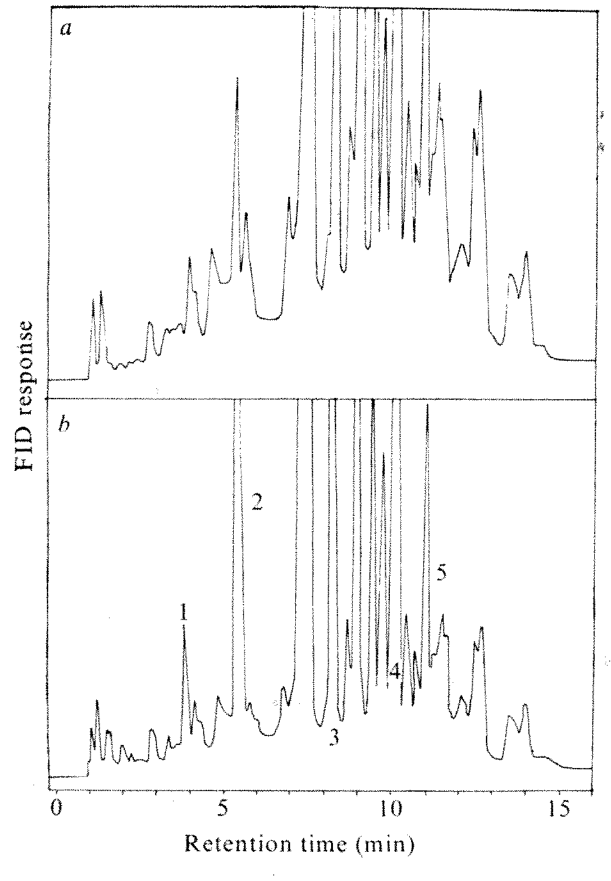

Fig. 2 Adsorption wire chromatograms obtained (as described in Fig. 1) from *a*, petrol sample from which 90% of the material had previously been allowed to evaporate in an open dish; *b*, from the original petrol sample. (Numbered peaks are referred to in Fig. 3.)

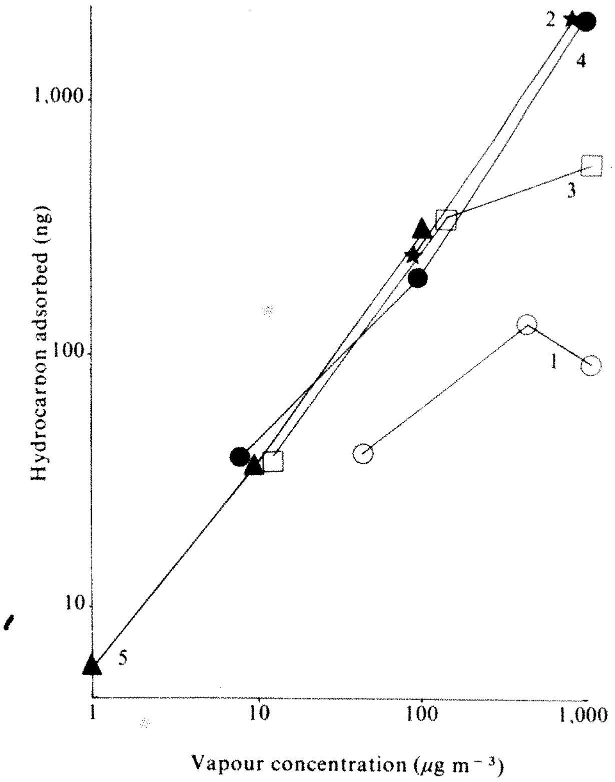

Fig. 3 Amounts collected by an adsorption wire versus vapour phase concentration for various species (log scales) after insertion for 1 h in a 100 l nylon bag containing known dilutions of petrol vapour in air. 1, Benzene; 2, toluene; 3, *o*-xylene; 4 and 5, trimethylbenzenes. Other aromatic species examined (not shown for clarity) fit the same calibration line as 2–5.

The ready adsorption of less volatile materials by the carbon overcomes the problems encountered by headspace analysis in dealing with residues which have been extensively evaporated in a fire. Figure 2 compares adsorption wire chromatograms obtained from a 90% evaporated petrol sample (Fig. 2*a*) with that from the original petrol (Fig. 2*b*). The only differences observed are at the more volatile end, the remainder of the chromatograms showing identical fine structure. This demonstrates the considerable advantages of the technique for the recognition of heavily evaporated accelerants in crime investigation.

Rapid adsorption of vapour phase components occurs with these wires, characteristic petrol traces being obtainable after only a few seconds immersion in a strong vapour. For the less volatile components of a paraffin headspace immersion for about 1.5 h is necessary to obtain a representative chromatogram, as the situation is complicated by adsorption on the vessel walls or in the debris. Where the vapours could not escape no further change has been observed in the wire chromatogram on longer periods of immersion.

The technique has been used successfully to identify petrol and paraffin residues in simulated fires with pine sawdust, when headspace analysis failed to produce recognisable traces. It has also been used as a rapid means of introducing retention index standards for calibrating Curie point pyrolysis GC. For this application the wires are held in the vapour space above each liquid sample for several seconds, separately for individual species, or sequentially for a series of materials. In this way the samples may be introduced in identical manner to that for the pyrolysis products, and changing of the inlet system is not required.

The technique has obvious application to air pollution analysis as a means of collecting and identifying components in a stack gas or other emission source. The method can be calibrated and has sufficient sensitivity for the quantitative monitoring of ambient air. Repeat experiments with the same wire immersed in equivalent volumes of known concentrations of petrol vapour in air gave the results displayed graphically in Fig. 3. Although the relationship between the amount adsorbed and the gas phase concentration was nonlinear, the adsorption characteristics of aromatic species studied were remarkably similar, with the exception of benzene. At levels exceeding $100\,\mu\text{g m}^{-3}$ (about 500 ng adsorbed on the treated wire) saturation effects began to appear for toluene and the xylenes, but below this level a calibration based on a mean line for all species (except benzene) would apparently result in errors of less than a factor of two. These results suggest that the technique may be used down to levels of $1\,\mu\text{g m}^{-3}$ which for the range of species examined is equivalent to 0.2–0.3 p.p.b. (volume parts per 10^9).

Depending on the species and site locations, city levels of these species lie in the range 0.3–130 p.p.b. (refs 1, 4, 8). Thus the method has the required sensitivity for ambient air monitoring although further work would be necessary to establish the performance of these adsorption wires in the dynamic environment of a city street.

The Asian source of Arctic haze bands

'Arctic haze' refers to turbid layers of air which are found regularly over the pack ice north of Alaska during periods of clear weather[1]. These layers are diffuse, hundreds to thousands of kilometres wide, 1–3 km thick, and can occur as single or multiple bands of different heights at nearly any level in the troposphere. They are invisible from the ground, but may limit horizontal and slant visibility within a layer to as little as 3–8 km. Their colour is grey–blue in the antisolar direction and reddish–brown in the solar direction, suggesting that they are true aerosol rather than ice crystals.

The initial, purely visual observation of Arctic haze were made more than 20 years ago. It was then forgotten about until 1972 when radiation measurements near Barrow, Alaska revealed unexpectedly high atmospheric turbidities, confirmed in 1974 (ref. 2). The anomalous turbidity was partly found in distinct layers at altitudes of only a few kilometres. About 40%, however, was above 4 km, the effective ceiling of the aircraft used.

The 1974 observations raised the question of possible anthropogenic origin of the haze, because rough trajectory analysis for a persistent haze period during March and April 1974 suggested that the air had passed over the north-eastern United States some days earlier. To check this possibility, we have used the chemical composition and morphology of the spring 1976 Arctic aerosol as indicators of its source, and concluded that it originated in the great Asian deserts. During April and May 1976 a series of 15 flights with a single-engine aircraft were made from the Naval Arctic Research Laboratory in Barrow, Alaska. Nine high-volume (90–360 m^3) samples of haze aerosol were collected on acid-washed 11-cm Whatman No. 41 cellulose filters. Nuclepore filter samples were taken concurrently for electron microscopy. Height of the haze layers was determined by a combination of visual observation, condensation-nucleus count, and turbidity profile.

The high-volume samples were subsequently analysed at the University of Rhode Island for a number of elements with short-lived nuclides by neutron activation, with results shown in Table 1. The month-long sampling period had very low elemental concentrations at the beginning, a strong maximum in the middle, followed by a sharp dropoff at the end. The high-concentration period coincided with visible haze bands, all of whose visual properties suggested Arctic haze. The bands did not come and go quickly; rather a single broad maximum of 6–13 days' duration was seen. During this period Al and Mn were increased in concentration relative to their initial and final values by over an order of magnitude, V by an order of magnitude, and Na and Ba by somewhat less than an order of magnitude.

The aerosol-crust enrichment factors (Table 1) for the elements

$$Ef_X(\text{Al, rock}) = (X/\text{Al})_{\text{aerosol}}/(X/\text{Al})_{\text{rock}}$$

showed similar trends of high values in the early samples which decreased smoothly to unity or lower with increasing haze aerosol. For V the trend was most marked; indeed of these elements V has the highest enrichments in cities (5–500 (ref. 3)). Taken together, the trends of these enrichment factors clearly indicated that the background aerosol was pollution-derived but that the haze aerosol itself was crustal, that is natural, just the opposite of what we had expected. Electron microscopy of the Nuclepore filters showed that angular crustal particles of diameter greater than roughly 0.4–0.8 μm are present in all samples, but with greatly increased numbers during the haze episode. In contrast, most particles smaller than 0.4–0.8 μm diameter were nearly spherical; their abundances were much less haze-dependent. Although we have studied only this one episode, we feel that it may well be typical, as discussed below.

The source of the crustal haze aerosol must be very strong to account for its high concentrations. It seems to be the great Takla Makan and Gobi deserts of eastern Asia. Upper-level constant-pressure charts indicate that our haze period was preceded by several days of intense air flow from these deserts to Alaska. Figure 1 shows the 700-mb isobaric trajectories for air arriving at Barrow before, during, and after the episode. Only episodic air had recently passed over the Asian deserts.

Several factors support the idea of an Asian source for Arctic haze. First, spring is the period of greatest dust storms in deserts. In our case, during nearly all of April 1976 the Asian deserts were filled with dust storms. Second, the composition of Arctic haze greatly resembles that of the Sahara aerosol (K. A. Rahn, L. Schütz, and R. Jaenicke, unpublished data). Third, flow patterns conducive to long-range transport from Asia to Alaska are strongest

Table 1 Elemental concentrations and enrichment factors for aircraft filter samples

during the spring[4,5]. Fourth, the Asian deserts are farther north than the other deserts, lying mostly between 40° and 50° North as opposed to the more normal desert latitude of 20° to 30°. Fifth, the length of typical trajectories between Asia and Alaska (9,000–12,000 km) is not out of line with the well documented 6,000-km path for transport of Sahara dust to Barbados[6].

An Asian source for Arctic haze explains or confirms many previous observations such as:

(1) Anomalously high turbidities over Barrow, especially during the spring[7] (flow patterns between Asia and Alaska appear to be common from November through May);

(2) The large size of the haze bands (see below);

(3) Previous haze events at Barrow (for example, the episode of March–April 1974 was preceded by a few days of strong flow from the Asian deserts);

(4) Previous measurements of anomalous turbidities over Fairbanks, Alaska. For example, 17–22 February 1976 was a whitish haze episode in Fairbanks which affected air at all levels and for which no explanation could be found. Visibilities were reduced from the normal 150 km to less than 30 km. Trajectory analysis now reveals that this air was also of Asian origin. Similar haze incidents with trajectories leading back to Asia seem to be a regular feature of the Fairbanks atmosphere during winter and spring;

(5) The accumulation of brownish insoluble deposits in the pack ice north of Barrow, which under examination with a light microscope seem to be continental dust (R. Paquette, personal communication). The mineralogy and possible sources of this dust have also been discussed[8];

(6) Anomalous ice-nucleus concentrations at College, Alaska, Blue Glacier, Washington, and Nagoya, Japan during February and March 1968, for which trajectory analysis showed eastern Asia to be the probable source[9];

(7) A case of abnormally high condensation nucleus concentrations at Barrow in March 1970[10], which was explained as pollution from Prudhoe Bay to the east but which may have originated from Asia because the large-scale flow for this period was from those deserts.

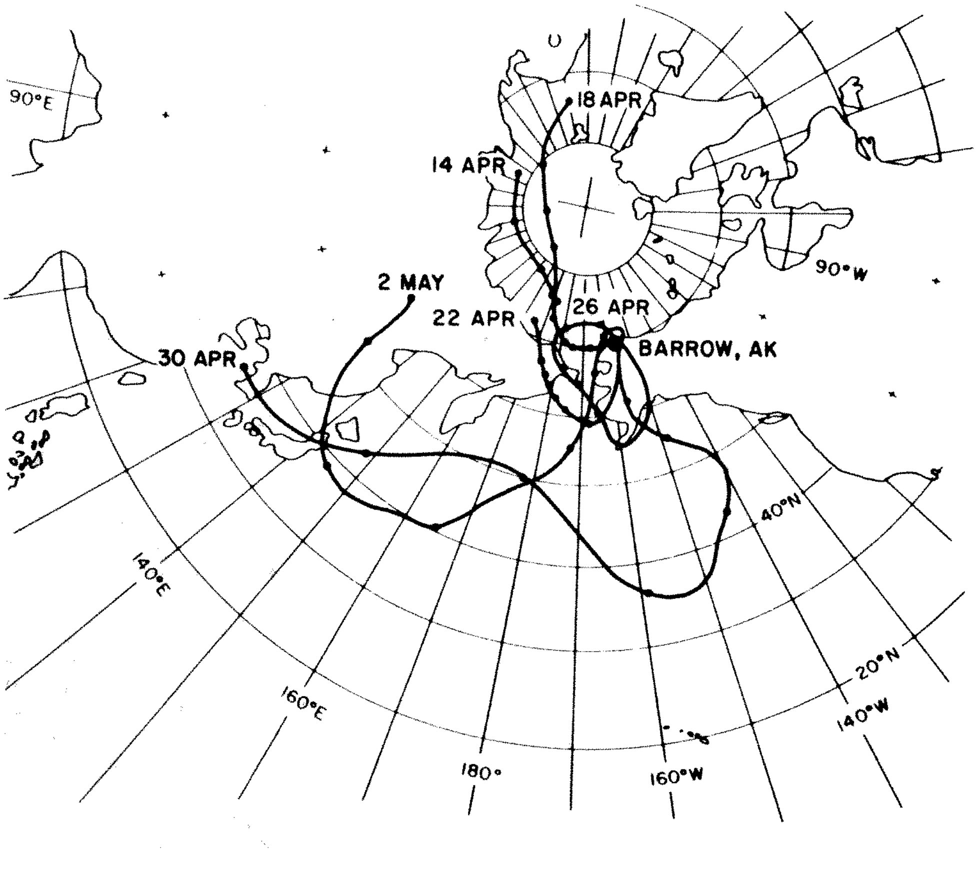

Fig. 1 700-mbar isobaric trajectories of air to Barrow. Numbers refer to date of arrival at Barrow. Solid circles each 24 hours along trajectory.

The mass of desert dust transported into the Arctic seems to be very great. For the five-day episode over Fairbanks discussed above, columnar mass loadings derived from radiation measurements showed values of about 45 mg m^{-2} (for aerosol density 2.5). For a point source in Asia and a dispersion angle of 5° (typical of volcanic plumes), the dust cloud would be 900 km wide at Alaska, or about the width of the state itself. (Indeed during this incident visibility was poor over the entire north half of the state.) Such a plume travelling at 80 km h^{-1} would carry 4,000 tons of dust into the Arctic per hour, or a half-million tons over the five-day episode. This is equivalent to skimming off a 0.2-μm layer from a 10° × 10° desert.

Clearly, more detailed studies are needed to refine our ideas about this significant phenomenon. Also, possible climatic effects of such large amounts of aerosol in the Arctic should not be overlooked.

This work was supported by Office of Naval Research (contract N00014-76-C-0435). The cooperation of many staff members of the Naval Arctic Research Laboratory, Barrow, Alaska is gratefully acknowledged. Samples were chemically analysed using facilities of the Rhode Island Nuclear Science Center, Narragansett, Rhode Island.

Sulphur dioxide discharge from Mount Etna

REMOTE sensing of SO_2 emitted by Mount Etna in its normal state of permanent activity, indicates much higher flow-rates than those previously measured by the same method (correlation spectrometry) on other volcanoes. A set of measurements in June 1975 provided a mean SO_2 flow-rate of 3,740 t d^{-1} for this volcano. This is a striking result both for volcanology and for environmental sciences. The knowledge of the mass discharge of chemical species from an active volcano and of its variations, both in time and space, is of great interest for the understanding of eruptive mechanisms and the establishment of geochemical balances. The SO_2 content of a volcanic plume can be measured from a distance by an optical correlation technique; this method was perfected a few years ago and has since been widely used for the remote sensing of air pollution in industrial areas[1]. During June 1975, we used the correlation spectrometer Barringer Cospec II to measure the SO_2 emitted by the active vents in the summit of Mount Etna (Central Crater, Bocca Nuova, North-East Crater and 1964 Crater), 3,200 m above sea level.

Activity within these craters was then characterised by a strong emission of condensed water vapour. From time to time, the plume issuing from the Central Crater was loaded with ashes produced by explosive activity taking place at least 500 m beneath the crater rim. At 2,600 m above sea level, on the northern flank of the volcano, the lateral eruption which had begun in February 1975 was still in progress, characterised by a slow effusion of an almost entirely degassed lava.

The remote sensing correlation spectrometer compares a high contrast reference spectrum (multiple slit mask) with the molecular absorption spectrum of the gas mixture examined (in the 3,100Å region for the sensing of SO_2). This correlation technique ensures the sensitivity and the selectivity of the instrument over a broad range of concentrations. The Cospec II displays the concentration times path length product of the SO_2 present along its optical path. In other words, the response of the spectrometer is directly proportional to the product p.p.m. (mean concentration of SO_2 in the sighted plume) × m (thickness of the plume) according to the Beer–Lambert's law. The skylight is the ultraviolet source for the spectrometer. Weak variations in the intensity of this source are automatically compensated; the stability of the instrument, in the absence of any cloud cover is maintained from three hours after sunrise until 3 h before sunset. Two quartz cells, containing the gas to be detected in two different concentrations, can be set on to the optical axis of the remote sensor: they are an internal calibration of the spectrometer. This internal calibration can be checked by sighting with the spectrometer just above the stack exit of a fossil fuelled power plant, whose SO_2 emission is accurately known (true scale external calibration).

On Mount Etna, measurements were made by the traverse method whereby the remote sensor equipped with its vertical sighting device is carried by car under the plume. A continuous westerly wind throughout our series of measurements provided the best meteorological conditions available on this site: the plume was drifting over a nearly straight motorway at sea level, 10 km downwind from the volcanic discharge area, on which the car could travel at constant speed between the cities of Giarre and Taormina. For each traverse, the signal of the spectrometer was recorded continuously. The SO_2 concentration of the plume appears on the strip chart as a nearly gaussian curve; its area is the product of concentration by surface (p.p.m. × m^2). From this measurement—corrected by taking into account the mean angle between the motorway and the plume axis —and from the mean wind velocity, one can deduce for each traverse the mass flow of the detected gas. The wind velocity was measured by teleanemometry. The teleanemometer used has been designed and constructed at Bradford University. It consists of an optical telescope and two photosensitive cells which measure the shifting rate of an illumination difference between two points of the field of the telescope. The signals of the two cells are treated on a digital correlator which can extract a mean delay time corresponding to the velocity of the sighted plume.

Table 1 displays the measurements from Mount Etna made during three days. The following conclusions can be drawn. When a main road exists near the base of a volcano, the traverse method ensures little dispersion of the measurements. Therefore, a systematic use of the optical correlation technique for the remote sensing of SO_2 could be used to detect slight variations of volcanic gaseous discharge that might indicate changes in eruptive activity.

Table 2 compares the mean values of SO_2 discharge from Mount Etna (17 traverses in 3 d) with those obtained from other volcanoes using the same technique. The flow measured from Mount Etna seems to be much higher than that measured from Central American or Japanese volcanoes, despite apparently similar activity (that is, moderate pyroclastic activiy) during the time of the measurements. Moreover, during violent pyroclastic activity, as emphasised

Table 1 SO_2 discharge from Mount Etna in June 1975

Date	Wind velocity ($km\ h^{-1}$)	Traverse number	Time (beginning of traverse)	SO_2 emission ($t\ d^{-1}$)
14 June 1975	30 (estimated)	2	11.00	4800
		3	11.30	3800
		4	12.30	3200
		5	15.00	2700
		6	15.30	3900
		7	16.00	3600
		9	16.30	4200
		10	17.00	3700
15 June 1974	36 (measured)	12	11.40	3300
		13	12.00	4200
		14	12.45	3800
		15	13.00	4000
18 June 1975	31 (measured)	1	11.00	4100
		2	11.35	3700
		3	12.20	3600
		4	14.25	3600
		5	15.00	3400

The normal permanent activity provides a very stationary SO_2 flow within the time scale used (duration of traverse under the volcanic plume: approximately 10min).

by previous authors correlation spectrometer measurements cannot be made because ash-laden plumes screen the skylight. For these two reasons, it seems hazardous to assume a global SO_2 discharge rate to the atmosphere for all cases.

SO_2 seems to be the main sulphur species in a volcanic gas plume emitted at high temperature and without a great amount of ash or condensed water vapour which could act as an oxidation catalyst and lead to the conversion of SO_2 into sulphates. This SO_2 prevalence is indicated by the generally low value of the SO_4^{2-}/SO_2 ratio obtained in volcanic gas plumes[2]. Measurements by Le Guern[3] on Mount Etna in June 1972 (activity similar to that of June 1975) showed that a sulphuric acid aerosol was emitted by the summit area of the volcano at a rate of 24 $t\ d^{-1}$. If as in fossil fuelled power plant fumes[4], SO_2 in volcanic discharge remains at this oxidation state for a long time as compared with the delay time between emission and observation, one can assume that the SO_2 flow accurately represents the total sulphur discharge of an Etna-like volcano. Hence, in order to measure the flow of all other chemical constituents of the volcanic gas phase, it is sufficient to measure their concentration in the plume against SO_2 concentration.

Nevertheless, the question of the oxidation rate of SO_2 in volcanic gas plumes during atmospheric diffusion is still unsettled. If this oxidation occurs more rapidly than mentioned above, then the flow rates reported in this paper are too low. In general, and essentially because of the light scattering by aerosols in the volcanic plume and in the atmosphere, all the SO_2 fluxes measured with the correlation spectrometer technique must be considered as minimums.

During our measurements of the SO_2 discharge from Mount Etna, the lava flow from the northern flank of the volcano had been estimated at $10^4\ t\ d^{-1}$. Assuming that 0.07% sulphur by weight is emitted by a basaltic magma while degassing[5], the estimated lava flow corresponds to a 14 $t\ d^{-1}$ SO_2 discharge from one of the summit craters of Mount Etna (in all likelihood the north-east one). This is far from the measured discharge and we may assume that the SO_2 originates from the degassing of a much greater mass of magma moving by convection within the volcano pipe. Using again the assumption of Moore and Fabbi[5], the mass flow of this convecting magma would at least represent $2.7\times10^6\ t\ d^{-1}$ ($\sim10^6\ m^3$). The more recent data[11] available on magmas more likely to reflect Etna's volatile content may suggest higher initial sulphur concentrations in the magma (up to 0.16% sulphur for basaltic liquids before effervescence). These data do not change the discrepancy between the observed lava effusion and the measured rate of outgassing.

Superheavy element fission hypothesis in carbonaceous chondrites

IN many meteorites, the abundances of the heavy isotopes of Xe are enriched relative to solar Xe. In some cases, this enrichment results from the addition of fission products from U and Pu. In some carbonaceous chondrites, however, the isotopic enrichment pattern of the heavy Xe is inconsistent with the measured Xe yield patterns of U, Pu, Cm, and Cf fission. The lack of correlation between heavy Xe enrichment and U concentration in separated mineral phases also argues that the Xe is not due to fission of an element whose chemical properties are similar to U. It has been suggested that this enrichment resulted from the decay of a superheavy element[1,2]. An experimental test of this hypothesis is proposed here.

Lewis *et al.* have determined that most of the trapped Xe in Allende and several other carbonaceous chondrites is contained in chromite, carbon and an unidentified phase, *Q*, which together constitute less than 0.5% of the total meteorite mass[3,4]. One component of this Xe is enriched in the heavy Xe isotopes, and Anders *et al.* consider this to be evidence for the decay of a now extinct, fissioning superheavy element associated with these minor phases[5].

In favourable circumstances, nuclear tracks produced by fission decay can be revealed by chemical etching or transmission electron microscopy. Flynn *et al.* have searched for tracks in chromite grains from Allende, and found none. They placed an upper limit on the *in situ* fission which is two orders of magnitude below that implied by the superheavy hypothesis[6]. Macdougall *et al.* examined an olivine adjacent to chromite in Murchison, selected from a separate which also contains the heavy Xe enrichment, and found no fission tracks[7]. These track studies, however, are inconclusive, since tracks in chromite and olivine might have been removed by a thermal event which would not have removed the Xe.

A more conclusive test of the superheavy fission hypothesis would be a search for fission related isotopic anomalies in other elements. These anomalies could be less affected by thermal events than the Xe anomaly or fission tracks. Furthermore, isotopic measurements could also be made on the carbon and *Q* phases, which are not suitable for track studies.

In samples of bulk meteorites, the fission contributions to elements other than Xe and Kr are too small to be detected because of the greater natural abundances of the other elements in solid materials. If, however, the extreme enrichment of heavy Xe in these minor phases of meteorites is due to fission there should be corresponding enrichments of other fission products.

The light rare earth elements are particularly well suited for a search for these isotopic enrichments because: (1) the natural abundances of rare earths are low; (2) the fission yields of rare earths are high; (3) the techniques for accurate mass spectrometric measurement of rare earth isotopic ratios have recently been developed, and (4) the constancy of rare earth isotopic ratios, except where altered by nuclear processes, has been established.

The fission decay properties of U and the transuranic elements help predict which elements should exhibit the largest isotopic anomalies from the possible superheavy decay. The mass yield data for spontaneous or thermal neutron fission of ^{235}U, ^{233}U, ^{239}Pu, ^{242}Cm, and ^{252}Cf all show a double peaked distribution with two rather broad maxima. The principal effect of an increase in mass of the fissioning nucleus is to shift the light mass peak to higher values, while the heavier mass peak remains essentially unchanged[8]. This behaviour, shown in Fig. 1, is explained by 50 proton and 82 neutron closed shell effects for nuclei on the heavy mass peak.

The heavy Xe yield data for Allende minor phases[9], when normalised to ^{136}Xe = 6%, fits well on the left side of the high mass peak (Fig. 1). This suggests that if the heavy Xe is of fission origin the relative yields of Ba and the light rare earths, which are nearby in mass, should be of the same magnitude as for the thermal neutron fission of ^{235}U, which has been well studied.

Using ^{235}U mass yields, we can calculate the quantity of each rare earth and Ba isotope which would be produced by the amount of fission required to give the observed heavy

Fig. 1 Mass yield curves for thermal-neutron fission of ^{233}U (——), ^{235}U (– – – –), ^{240}Pu (–·–·), and spontaneous fission of ^{252}Cf (····) (figure from ref. 17). ■, Yields of ^{136}Xe attributed to fission from the Allende Xe rich phases, normalised to ^{136}Xe = 6% yield (data from ref. 3).

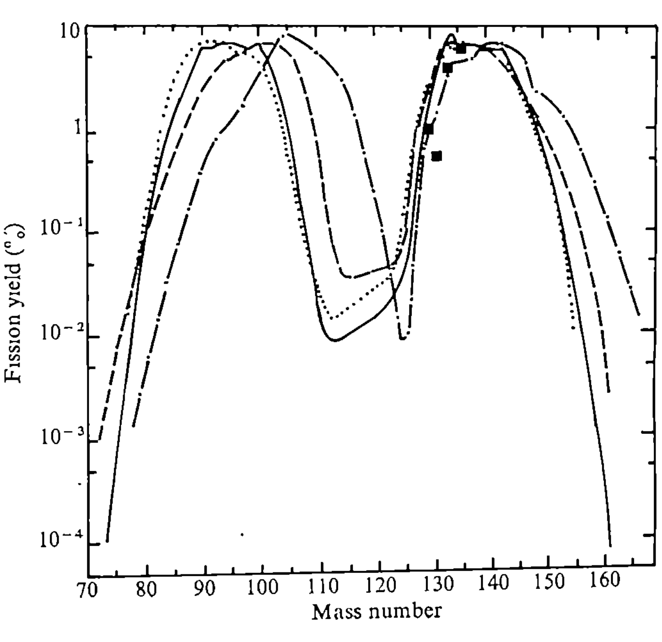

Table 1 Estimated fission induced deviations from normal isotopic ratios in the Allende Xe-rich phases

Isotope	Fission product*	δ(‰) Q	δ(‰) chromite	δ(‰) carbon

^{154}Sm	yes	+0.16	+0.02	+0.02

*This column indicates whether fission contributes to the isotope in question. The estimated isotopic enrichments and depletions are based on the assumptions that the yield curve is the same as for ^{235}U thermal neutron fission[8], the natural abundances of the elements are average carbonaceous chondrite abundances[15], and the natural isotopic ratios are terrestrial[16]. The quantities of fissiogenic ^{136}Xe in the Q, chromite, and carbon phases of Allende were taken as 3.7, 0.7, and 1.0×10^{-8} cm^3 STP g^{-1} (ref. 4).

Xe anomaly. Since the abundances of Ba and the rare earths in chromite, carbon, and Q from Allende have not been well established, we assume these abundances to be average chondritic and the natural isotopic ratios to be terrestrial. The deviations of the isotopic ratios from the terrestrial ratios due to the addition of fission products can then be estimated (Table 1). Several of these deviations are within the limits of detection reported by groups measuring the rare earths[9,10] and Ba[11].

Measurement of isotopic anomalies in these elements would confirm the fission origin of the heavy Xe. Should the progenitor be a known transuranic element, and the anomalous Xe some form of fractionated fission Xe, it might be possible to match the rare earth enrichments to the measured yields for a transuranic.

Should the progenitor be a superheavy, we might expect some broadening of the heavy mass peak, as seen for ^{252}Cf (Fig. 1), which would increase the yield of heavy rare earths. The yield of ^{156}Gd, for example, is 50 times greater from ^{252}Cf fission than from ^{235}U fision. Even larger amounts of ^{156}Gd might be expected from superheavy fission. Measurement of large isotopic anomalies in the heavy rare earths would suggest the progenitor was a superheavy. The absence of large isotopic anomalies in the heavy rare earths, however, would not eliminate the possibility of a superheavy progenitor. Ternary fission, which might not produce the heavy rare earths, has been suggested as a possible mode of fission decay for superheavy elements[12].

Other nuclear effects which might contribute to changes in the isotopic ratios are fission products from U and Pu, neutron capture production, and spallation. A U abundance of 100 p.p.b. has been measured in the heavy Xe-rich Allende separate (J. Shirck, personal communication), while Anders *et al.* have measured 3 p.p.b. in a chromite–spinel fraction of the Xe-rich separate[5]. Even using the larger 100 p.p.b. value and a Pu/U ratio of 0.016 at formation[13], the total contribution of U and Pu fission products over the 4.5×10^9 yr age of the meteorite is two orders of magnitude below the estimated superheavy contribution.

Neutron capture effects can be estimated from the ^{150}Sm/^{149}Sm ratio. Fission shielded ^{150}Sm is produced by a (n,γ) reaction on ^{149}Sm, which has the largest cross section of any Sm isotope. An upper limit on the neutron flux can already be set from the ^{80}Kr and ^{129}Xe measurements of Lewis *et al.*[3].

Isotopic contributions from spallation can be estimated from the proton flux, derived from spallation contributions to Xe and Kr, and measurements of the abundances of the various spallation targets.

The actual abundances of the rare earths and Ba in chromite, carbon, and Q have not yet been well established. However, Anders *et al.* report abundances for several rare earth elements in an Allende chromite separate to be depleted by about a factor of 5 from chondritic[5]. This would increase the deviations from natural isotopic ratios in the chromite phase by a factor of 5 from those given in Table 1.

Despite the elusiveness of Q, it might prove to be the most suitable phase for isotopic measurements since: it is most enriched in the anomalous heavy Xe, and it is soluble in nitric acid, providing the means for separation of Q and its associated rare earths from the chromite and carbon phases.

The technique of measuring rare earth isotopic enrichment patterns has already proved valuable in identifying the ^{235}U thermal neutron fission products in samples from the Oklo natural reactor[14]. Measurement of Ba and rare earth isotopic anomalies associated with the heavy Xe anomaly in carbonaceous chondrites could finally establish the fission origin of this heavy Xe. This technique would also be applicable to other samples where large concentrations of superheavy fission are expected.

We thank T. Bernatowicz, P. Fraundorf, F. Podosek, J. Shirck, R. M. Walker, and E. Zinner for helpful discussions. We also thank E. Anders who made useful suggestions in his review of this paper, and reported that he has privately suggested measurements of rare earth elements in these samples several times. This work was supported by the NSF (grant no. EAR 76-22697).

An early Cambrian chert biota and its implications

In the search for Precambrian life, much effort has been centred on the study of stromatolitic cherts and their predominantly blue-green algal flora[1]. Nonetheless, it is common for reviews of evolution of the biosphere to switch from consideration of Pre-Vendian chert floras to Vendian soft bodied or trace fossils and thence to Tommotian shelled invertebrates[2]. A more objective approach will involve tracing organic development across the Cryptozoic–Phanerozoic transition from within a single habitat. Until this has been attempted, our views of changing biotas will be obscured by the changing facies patterns. I report here the discovery of a new early Cambrian flora and fauna from a typically 'Precambrian' habitat, a chertified oncolite association.

The chert horizon occurs within parallel laminated dolomites about 10 m above the base of the Eilean Dubh Formation of the Durness Group of north-west Scotland, near to Inchnadamph (NC 253213). Except for an unverified report of *Salterella*[3] this is the first report of organisms from this predominantly dolomitic formation and confirms the early Cambrian age of the lower part. The underlying strata contain shelly fossils typical of Lower Cambrian rocks while overlying horizons within the Durness Group are of early Ordovician age[3].

The complex diagenetic history of these Durness dolomites[4] is evident from the varying degrees of organic and skeletal preservation in the Inchnadamph chert. Invertebrate skeletal remains, preserved in silicified dolomite clasts, have suffered much recrystallisation before silicification. Preliminary identifications of rare fragments show the presence of trilobites, hyolithids (Fig. 1*a*), sponge spicules and archaeocyathids (Ajacicyathacea). The presence of *in situ* invertebrates is indicated by pellet-filled burrows in the associated laminated dolomites.

Algal participation in carbonate accretion is shown by the abundant filamentous and coccoid structures preserved as kerogenous or pyritic material in ooliths and oncoliths (Fig. 1). Unbranched, septate filaments of 2–5 μm diameter occur as envelopes around oolith laminae and in the outer layers of oncoliths, mostly lying normal to the surface (Fig. 1*a, f*). These closely resemble recent and fossil filamentous blue-green algae from similar facies[5,6] and the mucilage probably contributed to oolith growth.

Branched filaments 1–3 μm in diameter occur as small, isolated and erect tufts up to 25 μm across, preserved in dark pyritic material (Fig. 1*b, d*). Their form and oncolithic habit compare closely with *Corbularia conglutinata* Vologdin from the Lower Cambrian of Asia[7]. The small cell diameter suggests cyanophyte affinities.

The problematic organism *Renalcis* is excellently preserved in several oncoliths, revealing forms comparable with *R. levis* Vologdin (Fig. 1*c*). This material is clearly not foraminiferid and resembles colonies of coccoid cyanophytes embedded in a gelatinous envelope (compare with *Anacystis*). I have previously argued in conjunction with Riding[8] that the 'chamber walls' of *Renalcis* cannot represent the single cell wall of blue-green alga, and here they are seen to consist of a chain of minute coccoid cells about 2 μm in diameter, their packing reduced towards the central 'chamber'. This, and evidence of shrinkage cracks in other material, leads one to support the blue-green algal interpretations of Korde[9] and Hofmann[10]. Nevertheless it is possible that *Renalcis* is an artificial and polygot genus, encompassing other algal and protistan groups.

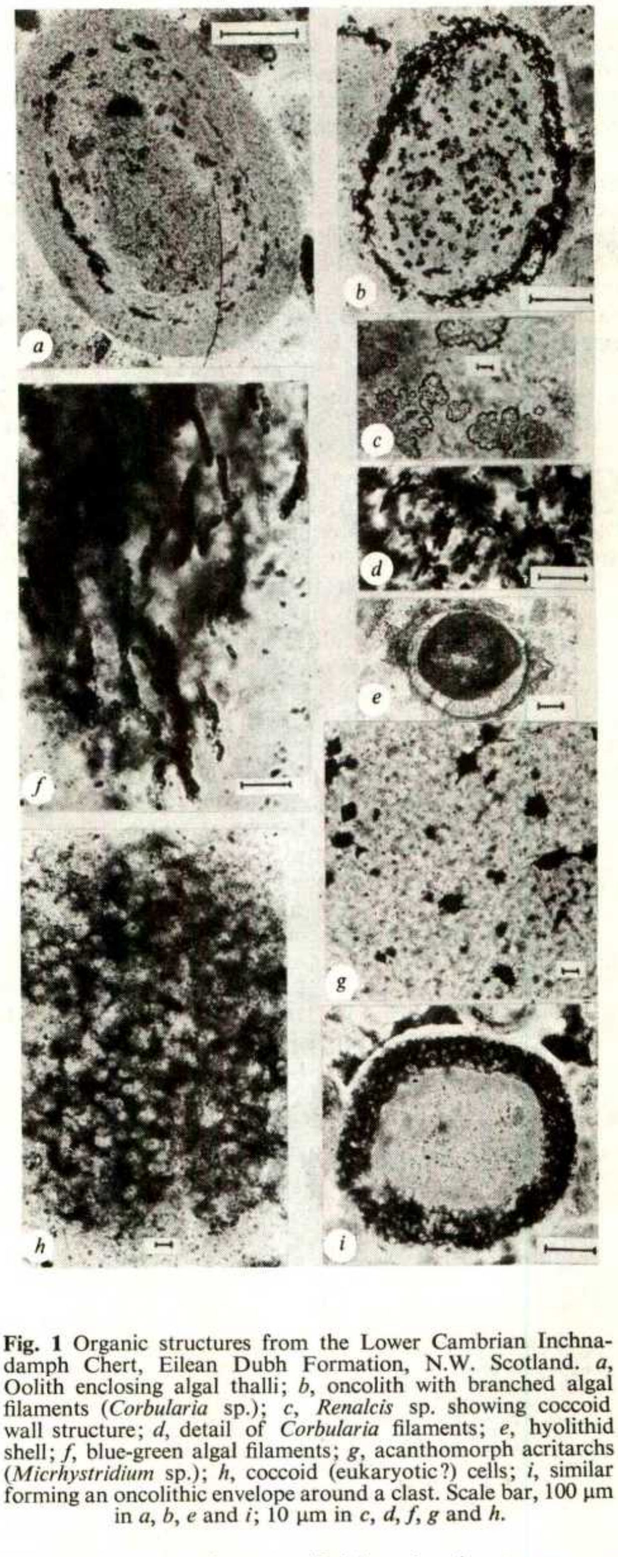

Fig. 1 Organic structures from the Lower Cambrian Inchnadamph Chert, Eilean Dubh Formation, N.W. Scotland. *a*, Oolith enclosing algal thalli; *b*, oncolith with branched algal filaments (*Corbularia* sp.); *c*, *Renalcis* sp. showing coccoid wall structure; *d*, detail of *Corbularia* filaments; *e*, hyolithid shell; *f*, blue-green algal filaments; *g*, acanthomorph acritarchs (*Micrhystridium* sp.); *h*, coccoid (eukaryotic?) cells; *i*, similar forming an oncolithic envelope around a clast. Scale bar, 100 μm in *a*, *b*, *e* and *i*; 10 μm in *c*, *d*, *f*, *g* and *h*.

Larger coccoid cells 12–25 μm in diameter are probably eukaryotic (Chlorophyta?). These occur singly or as colonies coating the outer margins of round carbonate clasts (Fig. 1*h, i*) and occur throughout some oncoliths. Cell walls and contents are not preserved, their form merely being outlined by strongly pigmented material that was once a mucilaginous matrix (compare ref. 10). Acanthomorph acritarchs 12–20 μm in diameter (*Micrhystridium* sp.) are evenly distributed through a few silicified dolomite clasts (Fig. 1*g*) where they are associated with archaeocyathid fragments.

The scarce invertebrate remains, acritarchs and *Renalcis* suggest that sediments were deposited in an offshore facies, perhaps like that of the Forteau Formation of Newfoundland with which this horizon could be correlated. The oncolithic flora clearly shares with its Precambrian precursors an inferred abundance of blue-green algae but differs in the predominance of tufted forms such as *Corbularia*. While the growth forms of *Renalcis* can be matched with coccoid cyanophytes from the Precambrian[10], their expansion in biohermal facies was clearly a Phanerozoic, Tommotian event[7] as was the radiation of spiny acritarchs[11]. Comparisons with similar late Precambrian biotas indicate that innovations were taking place in the Cambrian oncolite habitat. Invertebrates had begun to graze and burrow extensively, as predicted by Garrett[12]. Coccoid eukaryotes had developed the oncolithic mode of growth. Even the ultraconservative prokaryotes show a radiation of oncolithic forms, including skeletal oncoliths like *Girvanella*[13], and biohermal forms like *Renalcis*.

Evidently the 'Cambrian evolutionary explosion' was not confined to metazoans, to eukaryotes or to skeletal forms. Old 'Precambrian' niches remained but were modified. The simplest explanation for these wide-ranging changes is an ecological one, based on the cropping principle[14,15]. Increased grazing pressure by microphagous benthic organisms brought not only a general diversity increase but also the associated phenomena of skeletalisation, size increase and burrowing. Skeletalisation is seen, amongst the present biota, in the spiny cuticularised wall of the acritarchs, which may have served to resist digestion by deposit feeders. Permineralisation and size increase in early Cambrian algae would have performed a similar function, to discourage overcropping by herbivores. The disruption of stromatolite growth by burrowers is also seen and must have favoured the development of unattached oncolithic algae like *Corbularia* and *Girvanella*. Further searches may reveal the soft tissues of invertebrates of the same age preserved in this or similar cherts.

I thank Professor M. R. House for collecting additional field data and material and Drs J. W. Cowie, M. D. Muir and C. M. Brasier for their comments.

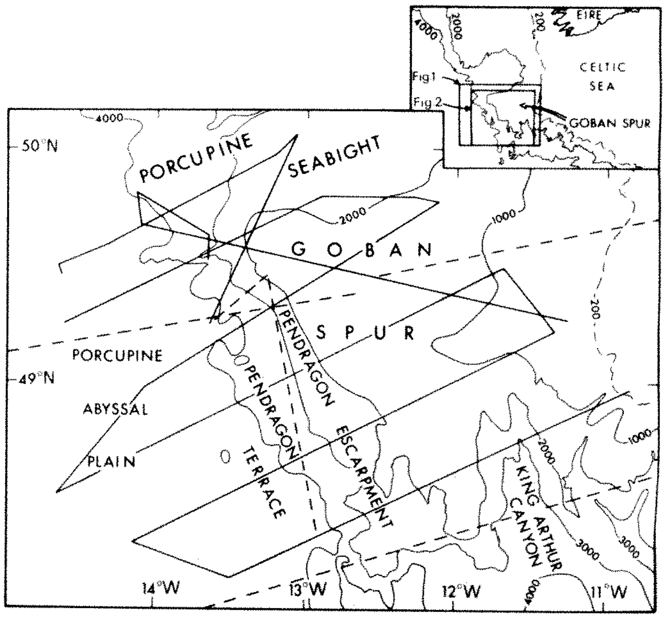
Continental margin fault pattern mapped south-west of Ireland

A SIMPLE model for continental basement structures at rifted continental margins comprises large fault blocks which trend approximately parallel to, and step down towards, the continental–ocean boundary (for example, see ref. 1). These blocks may be cut by faults which strike across the margin, and, in many theoretical discussions, are shown as being separated from the true oceanic crust by an intermediate zone (see transitional crust of Fig. 3, ref. 2). On many rifted margins these features are deeply buried by young sediments and cannot be stutied in detail. On Goban Spur (Fig. 1), a marginal plateau south-west of Ireland, the young sediment cover is abnormally thin, however, and we have been able to map in detail a 150 km wide continental basement fracture pattern of horsts and grabens using a simple seismic reflection system (160 inch^3 air-gun and two-channel hydrophone array). We also suggest a location for the continent–ocean boundary between the Spur and Porcupine Abyssal Plain. There are few previously published data from Goban Spur relevant to our study, although valuable sampling[3] and geophysical[3–5] results have been obtained north and south of the area.

The results of our surveys (Fig. 1) indicate a threefold subdivision of the continental margin from east to west: block-faulted continental basement (Goban Spur); intermediate zone (Pendragon Terrace); and oceanic basement (Porcupine Abyssal Plain) (Figs 2 and 3). North of 49°N the margin is cut by at least two large fault zones (fault zones 1 and 2), to the south of which the threefold subdivision is most easily recognised. Beneath the central and southern parts of Goban Spur, there are several large, north-west–south-east trending basement highs. These are most probably fault bounded, and are separated by basins containing relatively thick sedimentary sequences (>1.5 s double time). The amplitude of the basement discontinuities between high and basin is generally between 1 and 2 s double time, with the mean depth to basement decreasing from west to east. Alhough there is some evidence for rotaion of the fault blocks (for example, at 49°00′N, 12°40′W), our data best fit a model of ridges or horsts and grabens. Sample evidence indicates that the basement highs and, probably, the whole basement beneath Goban Spur, is continental in composition (granitic, metamorphic and old sedimentary rocks—ref. 3 and our unpublished data).

Goban Spur is separated from the continental shelf and the Pendragon Terrace by large boundary discontinuities, presumed to be faults (inner boundary fault and Pendragon Discontinuity respectively). The amplitudes of these dislocations are about 2.0 and 1.5 s double time respectively, and although the latter is not particularly large it does coincide with a change in basement characteristics. Our

Fig. 1 Track chart of seismic lines occupied by RRS Shackleton over Goban Spur during cruises 5/76 and 4/77 (- - - -, bathymetry only). Bathymetry in m after various sources. Inset shows location of Figs 1 and 2.



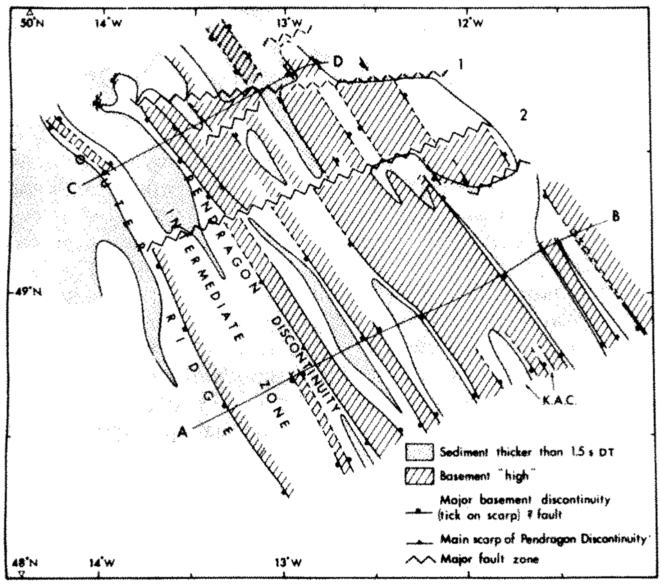


Fig. 2 Summary structural map of Goban Spur and adjacent areas, K.A.C., King Arthur Canyon. Sections AB and CD are shown in Fig. 3.

gravity data indicate that it also marks the point of maximum change in thickness of the crust. Where the Pendragon Discontinuity acts as a sediment dam it underlies a prominent bathymetric feature called Pendragon Escarpment, but in the south, the escarpment lies about 10 km west, over a subsidiary ridge.

The Pendragon Discontinuity separates Goban Spur proper from the intermediate zone. Here, basement morphology is relatively subdued (0.5 s double time in amplitude), and generally lies about 1.0 s double time deeper than to the east. The basement of the intermediate zone south of fault zone 2 is covered by a relatively thin sedimentary sequence, and although we have no sample evidence for its composition, geomagnetic characteristics suggest that it is largely similar to that beneath the spur. A large magnetic anomaly occurs, however, over the outer part of Pendragon Terrace, indicating the presence of basic igneous rocks. An outer ridge (Fig. 2) separates the intermediate zone from oceanic crust under the Porcupine Abyssal Plain, where basement morphology is rough but of low amplitude. The depth to oceanic basement is about 7.0 s double time and the sediment cover is relatively thin. Linear magnetic anomalies resulting from regular seafloor spreading are not well developed until 14°30′W is reached, although the magnetic field is rough and indicative of oceanic basement. We tentatively identify the western flank of the outer ridge as the location of the continent–ocean boundary.

Having briefly described the tripartite division of the margin structure where it is most clearly developed in the south, we now consider the northern part of Goban Spur, where the fracture pattern is crossed by fault zones 1 and 2 (Fig. 2). Fault zone 2 is a complex structure. Beneath Goban Spur it seems to act as a scissor fault, throwing the crest of the Pendragon Discontinuity up to the north, but the general level of basement to the east of the discontinuity down to the north. The fault also causes an alteration in the strike of the Pendragon Discontinuity (making it more westerly), coincides with an increase in amplitude of the discontinuity to about 4.0 s double time, and displaces it slightly in a dextral sense. Beneath Pendragon Terrace, however, zone 2 appears to act as a simple fault throwing down to the north. The depth to basement in the intermediate zone increases from about 5.5 s to about 7.3 s double time across the fault. Evidence that fault zone 2 has influenced the development of oceanic basement under the nearby parts of Porcupine Abyssal Plain comes from magnetic anomaly data, which show that sea-floor spreading anomalies are better developed to the north of the fault. An increase in sediment thickness in the abyssal plain is also observed across the westward extension of fault zone 2. Despite these complexities we can confidently recognise the tripartite subdivision of the continental margin between fault zones 1 and 2.

Fault zone 1 constitutes the northern structural boundary of Goban Spur. To the north of this, basement highs and lows are down-faulted into the southern part of Porcupine Seabight, so that the general level of basement is 2–3 s double time deeper. The thickness of the sedimentary sequence increases rapidly across the fault zone. Although the general structural pattern of Goban Spur can be traced into Porcupine Seabight, it is not possible to follow individual features, such as the Pendragon Discontinuity, and hence we do not know if there is any strike-slip component of motion on fault zone 1. The horst and graben style of tectonics identified beneath Porcupine Seabight has approximately the same trend as that beneath Goban Spur and may owe its existence to the same phase of rifting.

We believe that we have mapped a continental margin fracture pattern some 150 km wide that was initiated during the rifting phase that preceded the opening of the North Atlantic Ocean at this latitude. The trend of the basement horsts and grabens is parallel to the seafloor spreading magnetic anomalies observed further west[6]. On the evidence of these anomalies, the opening of the North Atlantic hereabouts is thought to have begun in Upper Cretaceous times. This would suggest that the rifting phase is of Cretaceous age. Our records show that there has been little or no vertical movement between adjacent fault blocks since the rifting phase. Thus, the subsequent history of the margin is one of overall limited subsidence. There is good evidence for Goban Spur being underlain by Hercynian granites[3,7], whose relative buoyancy in the crust could account for the lack of subsidence and thin sediment cover. Fault zones 1 and 2 are approximately parallel to the Hercynian structural grain projected from areas surrounding the Celtic Sea. Apparently, the rifting tectonics have been modified by reactivation of these old trends to produce the observed fracture pattern.

The assistance of the Master, officers and crew of RRS Shackleton and technical support of I.O.S. (Barry) are

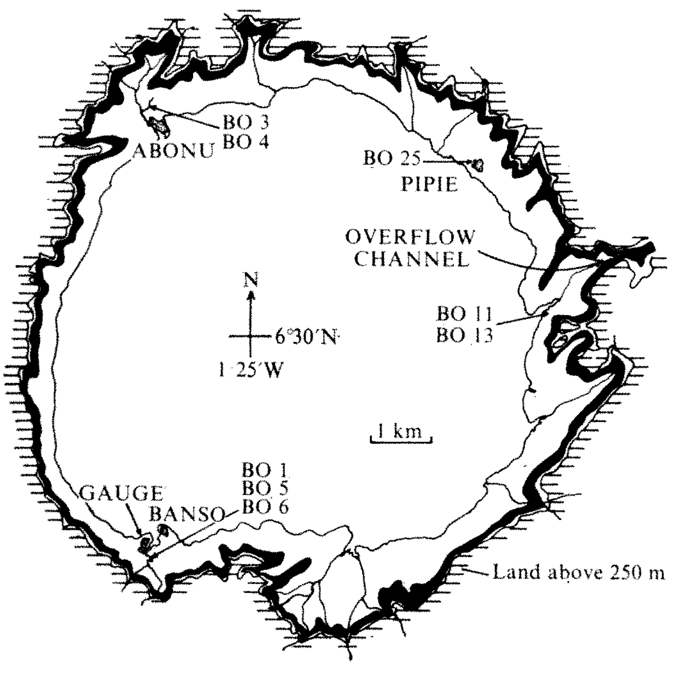
Holocene variations in the level of Lake Bosumtwi, Ghana

RECENT surveys of the changing climate of Africa during the Late Quaternary have shown that although a reasonably well established climatic sequence is now available for some parts of the continent, there exist very large areas which have yet to yield any well-dated, unequivocal palaeoclimatic data[1–3]. Most notable among the latter are the lowland tropical forest regions. Despite the absence of information from such critical areas, attempts have been made to reconstruct atmospheric conditions over West Africa during the Late Quaternary[2,4,5], but obviously no uniformly satisfactory models can be produced until these data gaps have been filled. Study of changing lake levels has proved a particularly valuable palaeoclimatic tool[3] and we report here the first ^{14}C dates of former levels of a lake that lies within the present lowland forest zone of West Africa. Our work indicates that lakes of the humid tropics can provide valuable palaeoclimatological information that may be less apparent from the study of arid zone lakes. In particular, we present evidence suggesting that major regressions of equatorial African lakes during the Holocene, rather than being a consequence of exceptional aridity, may have occured during periods of slightly higher temperatures and greater evaporation.

Fig. 1 Map of Lake Bosumtwi and inner part of crater, showing location of samples detailed in Table 1. Solid band below 250 m is erosional bench at level of overflow channel.



Lake Bosumtwi lies within a steep-sided crater that was produced by meteoritic impact 1.3±0.3 Myr ago[6]. The lake has a maximum depth of about 80 m, and in 1976 its surface lay at +100 m OD, some 105 m below the lowest point in the surrounding rim of hills and 100–200 m lower than the land outside the crater. Maintenance of the lake is thus largely dependent upon rainfall over the crater, a catchment of about 400 km^2. Mean annual precipitation is 1,520 mm and temperature 26 °C.

A clearly defined wave-cut bench encircles the lake at about 110 m above present lake level and merges into the lower slopes of the valley that provides the lowest point of exit from the crater (Fig. 1). This, the only valley to cut cleanly through the crater rim, has obviously functioned as an overflow channel in the past. No material suitable for dating has been found here, nor on the bench, all the dated samples coming from lacustrine sediments exposed within +25 m of the present lake surface.

Sample sites are shown on Fig. 1; samples and their ^{14}C ages are summarised in Table 1. On the basis of these results, plus historical records[7,8] and data from the Geological Survey Department's gauge at Apewu (1933 onwards), an attempt has been made to reconstruct the behaviour of Lake Bosumtwi over the past 10,000 yr (Fig. 2). Sediments older than the turbidite silts (Table 1) have not been identified[9]. This is somewhat surprising in view of the relative antiquity of the lake, particularly as the strong development of the high bench and overflow channel testify to one or more prolonged periods of maximum lake level.

The Holocene behaviour of Lake Bosumtwi shows some similarities with lakes elsewhere in West and East Africa. Generally high levels are known to have occurred throughout the tropics during the early Holocene[2,3]. In the case of lakes that occupied basins in what are now arid or semi-arid regions, the climate must have been markedly wetter then than now. Even though Bosumtwi was also high at this time it cannot be demonstrated that precipitation here was necessarily greater than at present. The lake has been rising continuously for at least the past 120 yr (Fig. 2), so prevailing climatic conditions seem adequate to maintain a very high level. Indeed, if evaporation from the lake surface is taken to be about 1.45 m yr^{-1} (ref. 10) (mean annual pan evaporation at Kumasi, 30 km away, was 1.4 m over the period 1954–1974), then a simple mass balance calculation is sufficient to show that the present hydrological regime is capable of sustaining the lake at overflow level. It is thus possible that around 9,000–10,000 yr BP the climate was essentially similar to today. Abundant leaf impressions preserved in the turbidites indicate that although the forest flora may have differed slightly in composition from modern local forests, the climate of the early Holocene must have been comparable with the present[11].

Unfortunately, we have been unable to obtain dateable material from the upper part of the turbidite silts and so have no precise idea how long the very high stand persisted. The considerable thickness (~ 35m) of silts above the dated horizons at Banso suggests that it continued well into the Holocene. The regression that followed clearly involved a considerable fall in lake level, the resulting erosion surface having been identified at elevations ranging from +2 m to +18 m. The subsequent transgression was coeval with positive changes in level that are known to have occurred in lakes throughout tropical Africa around 2,000 yr BP–3,000 yr BP (refs 2 and 3).

Table 1 Summary of samples* with ^{14}C ages

Sample no. locality	Lab. no.	Nature of sample	Geological context	State of lake	^{14}C age (yr b.p.)
B01 Banso	GIF—3650	Wood	Turbidite silts	Very high > +35 m	9880±220
B05 Banso	GIF—3991	Wood	Turbidite silts	Wood accumulated in deep anoxic waters of a stratified lake	10000±220
B03 Abonu	GIF—3651	*M. tuberculata*	Deltaic sands	Moderately high ~ +23 m	2520±200
B04 Abonu	GIF—3652	*M. tuberculata*	Deltaic sands	Moderately high ~ +25 m	1940±300
B06 Banso	GIF—3992	Wood	Root penetrating turbidite silts	Rising, vegetation killed by transgression	3620±110
B013 Konkoma	GIF—3996	Wood	Remnants of vegetation that colonised exposed turbidite silts		3020±110
B011 Konkoma	GIF—3995	*M. tuberculata*	Deltaic sands	Moderately high ~ +18 m	700± 90
B025 Pipie	GIF—3998	*M. tuberculata*	Silt between granite boulders	Moderately high > +19 m	1650±110

*Used in preparation of pre-nineteenth century section of Fig. 2. For precise sample localities see Fig.1.

Historical records[7,8] and the oral traditions of fishermen living around the lake are consistent in indicating that 200–300 yr ago Bosumtwi was very low indeed. The geological evidence for moderately high levels persisting until around 700±90 yr BP implies, therefore, that a rather abrupt regression must have started in the thirteenth or fourteenth century. In attempting to understand the regression of Bosumtwi, it is helpful to compare the behaviour of the lake with trends established for other climatic zones in West Africa, comparative palaeoclimatic data from elsewhere in the forest zone being nonexistent. Over the period of systematic observation, variations in the rate of rise of Bosumtwi have closely matched variations in the precipitation of the Sahel[12] (Fig. 3). Although climatic oscillations in the two regions may not always have progressed in unison (ref. 13 and J. Maley personal communication), the Sahel can provide a particularly sensitive indication of changes in the precipitation brought by the monsoon. Figure 3 shows, for example, that the Sahelian drought of the late 1960s and early 1970s was clearly reflected in Lake Bosumtwi by a period of lower than average rises. The lake, however, continued to rise, showing that this region of the forest was not exposed to true drought. Obviously here regression is only to be expected when monsoonal precipitation is drastically reduced and the Sahel subject to prolonged and exceptional aridity. This observation is of considerable importance in understanding the behaviour of Lake Bosumtwi in the more distant past.

Looking first at the period between 700 yr BP and the present, there is evidence to suggest that during the seventeenth and eighteenth centuries parts of the Sahel were slightly moister than at present[14], while there was at least abundant rainfall in the Chari–Logone catchment with which to maintain Lake Chad at very high levels[13]. At the same time, by analogy with the twentieth century, Lake Bosumtwi should have been very high or rising rapidly. The latter would certainly be consistent with oral traditions, which although indicating low lake levels, also abound with references to lake shore villages being abandoned because of inundation[7,8]. Thus the last regression must have occurred between the thirteenth and sixteenth centuries.

Over the last 1,000 yr Lake Chad is known to have oscillated considerably in level. A number of regressions are recognisable, including one which started between the twelfth and thirteenth century[4,13] and may, therefore, have been synchronous with the last fall of Lake Bosumtwi. None of these low stands of Lake Chad, however, seem to have been of long duration, the latest accompanying the recent drought and the last three occurring within the past 150–175 yr (ref. 15). Throughout this period, Bosumtwi has risen continuously, so monsoonal precipitation in the forest zone can clearly never have been greatly reduced during the nineteenth and twentieth centuries, despite decreases on a scale sufficient to allow Lake Chad to fall. As the twelfth to thirteenth century regression of Lake Chad was of apparently comparable magnitude with these more recent

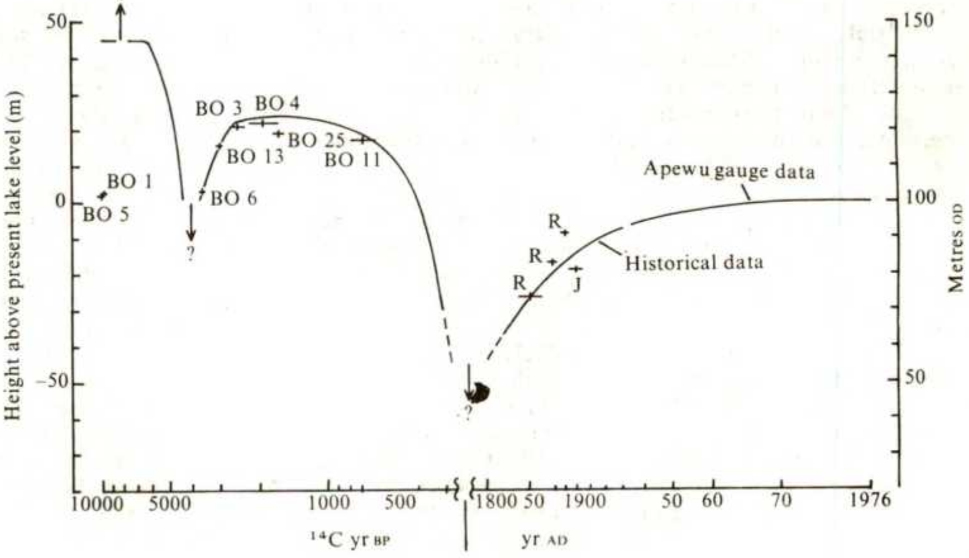


Fig. 2 Holocene fluctuations in level of Lake Bosumtwi (BO). Curve constructed from: (1) ^{14}C dates of samples described in Table 1; (2) historical reports of changes in lake level during the nineteenth and early twentieth century; (3) Apewu gauge data (1934 to present). Horizontal bars represent error on dates (standard error for ^{14}C; estimated range for historical dates). R, dates from ref. 9; J, date from ref. 8. Note log time scale.

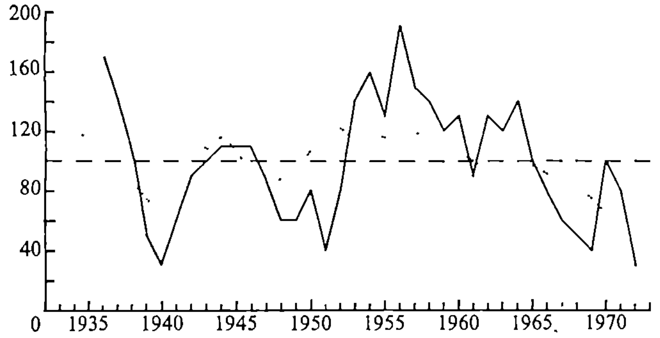

Fig. 3 Five-year running means of monsoon rainfall in the Sahel zone (from ref. 16, Fig. 2) and increments in the level of Lake Bosumtwi (from Apewu gauge record), both expressed as percentage deviation from the mean. . . . . Sahel; ——Lake Bosumtwi.

falls, there seems no reason to suspect an exceptionally different rainfall regime at that time, either. The abrupt decline of Lake Bosumtwi is unlikely, therefore, to have been the result of drastically lower rainfall, but was more probably due to the combined effects of a rise in temperature and accompanying slight decrease in precipitation inducing evaporation losses to exceed water input. An inverse relationship has been demonstrated to exist between temperature and precipitation in some parts of tropical Africa[4,16]. In the Bosumtwi region, during the 1967–1974 dry period, annual precipitation was 92% of the 1932–1974 mean, but temperatures were around 0.2 °C higher than the long-term average. If 1967–1974 conditions were to become the norm, a further rise in mean annual temperature of only 0.5 °C might be sufficient to cause the transition to a negative hydrological balance[10]. As such a rise would probably be accompanied by an even greater decrease in rainfall, it is obvious that only a slight deviation from climatic conditions that have prevailed at times during the twentieth century would be necessary to initiate a regression of Lake Bosumtwi.

Evidence of elevated tropical temperatures in the twelfth and thirteenth centuries should not be altogether unexpected. This was a period of maximum solar activity[17], and there are abundant indications of notable warmth in the temperate northern hemisphere during late Mediaeval times[18–20]. Records of much reduced discharge of the Nile, which must in part have been due to lowering of the great lakes of East Africa[21,22], are perhaps further testimony to accelerated evaporation in the equatorial zone at that time, while climatically-induced environmental stress during the thirteenth and fourteenth centuries may also have been responsible for the rather sudden migration of pastoralists from the Bahr-el-Ghazal region of the Sudan southwards into Uganda[23]. Lamb[16] has observed that the conjunction of lowered equatorial rainfall with periods of increased temperature, and thus greater moisture input into the atmosphere, must imply significant transport of moisture out of the equatorial zone. Such a process could have been particularly intense during the late Mediaeval thermal optimum, when poleward displacement of moist tropical air may have helped bring about the widely reported exceptional precipitation that affected higher latitudes at that time[18–20].

Identifying the cause of the mid-Holocene fall of Lake Bosumtwi must await more precise dating of this event. It was probably coeval with the general decline of African lakes, Saharan, Sahelian and equatorial, which commenced between 6,000 yr BP and 5,000 yr BP[1–3]. Diverse sorts of evidence indicate that the period 6,000yr BP–4,000 yr BP was everywhere characterised by relative warmth[20,24,29], so elevated evaporation rates are likely to have played an important part in the fall of Lake Bosumtwi at that time as well.

M.R.T. thanks the University of Ghana, Legon for financial and material assistance while in the field, and the Director, Geological Survey Department of Ghana, for access to the Apewu gauge records. Valuable comments and criticism were provided by Jean Maley, USTL, Montpellier, and Martin Wililams, Macquarie University.

Final results of study of infants at risk of sudden death

IN 1974 we described how we had used routine obstetric and perinatal records to construct a scoring system for identifying within 24 h of birth infants at risk of dying unexpectedly, and we reported the results of the first year of a prospective evaluation of the system[1]. We now have the final results of the study which confirm that the scoring system is effective. The study data and subsequent work suggest that deaths can be reduced by increased surveillance of high risk infants.

The scoring system used combined observations of eight variables[2]—mother's age and blood group, whether she was reported as having a urinary infection or polyhydramnios during pregnancy, the duration of the second stage of labour, the birth order of the infant, whether it was premature, and whether the mother intended to breast feed. Increasing age of mother, blood group A and breast feeding were associated with low risk. The high risk infants were not identified by single factors as is the common practice[3–5] but by the weighted combination of all observations.

The organisation of the prospective study[6] was briefly as follows. Each week day the score of each new baby was calculated. Babies born at home were included. Infants scoring above the estimated 85th quantile were designated high risk. After excluding high risk infants with gross congenital anomalies, the high risk infants were randomly allocated to 'observation' or control groups. At certain times because of holidays, all high risk infants were allocated to the control group. The observation group were invited to participate in the study. This comprised a clinical examination made within 48 h of birth, a second at 5 weeks, together with 10 visits to the home spread over the first 20 weeks of life by specially appointed health visitors. Half of the infants who dropped out of the follow-up study are included in the study group and half with the refused. All babies born in 1973 and 1974 in the County Borough of Sheffield, as defined before the local government reorganisation, were included in the prospective study. By the end of 1976 all these infants were at least 2 yr old, the generally accepted upper age limit for the occurrence of unexpected infant death[7].

The results are summarised in Table 1. A total of 11,424 infants were scored. Our count for 1973 differs by 6 from that published by the Office of Population Censuses and Surveys. Due to local government reorganisation no official figures are available for the study area for 1974, but our study continued unaltered and we think few if any babies were not scored. In all 15.7% of infants were scored as high risk.

Table 1 Post perinatal infant mortality, that is, 1 week—1 year, in various groups of the prospective study.

	No. in group	Probably unpreventable deaths	Unexpected deaths	
			No.	‰ of group
High risk				
Observed	627	1	2	3.2
Control	922	4	9	9.8
Refused	210	—	3	14.3
Excluded	35	12	1	—
Low risk	9,630	12	15	1.6
Total	11,424	29	30	2.6

Deaths are shown under two headings, probably unpreventable and unexpected deaths[8]. Post-mortem assessments were made without knowledge of the high risk grouping. Deaths due to anomalies, for example congenital heart defect, tumour or Werdig-Hoffman syndrome together with deaths of infants who never left hospital are shown as probably unpreventable. One high risk infant excluded and kept in hospital several weeks because of a suspected congenital heart defect, died unexpectedly a week after discharge, but the anomaly could not be demonstrated post mortem. Table 1 shows that the unexpected death rate in the high risk control group is more than 6 times that of the low risk group (relative risk 6.3). This difference is unlikely to occur by chance ($P < 0.001$), and shows that the scoring system is highly effective. The relative risk of unexpected death in the group that refused is 9.2 and is also statistically significantly greater than 1, $P < 0.001$. The relative risk of the observed group is only twice that of the low risk group.

Between the age of 20 weeks and 1 yr there were three unexpected deaths, one in the high risk control group and two in the low risk group. In addition, there were five unexpected deaths between the ages of 1 and 2 yr, one in each of the first three high risk groups and two in the low risk group. The results are therefore essentially the same if the data are examined at 20 weeks, at age 1 yr as in Table 1, or at 2 yr. Overall these final results are remarkably similar to those previously reported[1].

The possibility that surveillance reduces mortality requires comment. The difference between the unexpected death rate in the studied group and the high risk control group is not statistically significant using a χ^2 test. If we group those who refused surveillance with the controls, the chance of a difference as large or larger, using an exact one-sided test of significance, is 0.076.

Our primary objective was to observe the high risk group, but to ignore serious medical conditions would have been unethical. By special arrangement our team of visitors were allowed to take infants directly to hospital if necessary and when the 5 week clinical examination showed that bottle feeds were often over-concentrated[9] active steps were taken to ensure that feeds were correctly made up. It is possible to dismiss the reduction in the unexpected death rate in the study group as non-significant, as Magura has done[10], but the alternative hypothesis that the death rate is reduced is more likely.

The difference between study and control groups is also less different than might be expected because all groups benefited from the study, for example, the campaign to explain the dangers of overstrength feeding was not confined to the study group. The benefit is reflected in a reduction in the post perinatal mortality rate. For 1968–1972 the average post perinatal infant mortality rate for Sheffield was 8.2 per thousand, compared with a rate of 7.6 per thousand in England and Wales in this period. For the study period the rate was 5.2 per thousand—England and Wales 7.4. Had the observed group had the same mortality rate as the control group, the rate would have been 5.7 per thousand. On the other hand, if the benefits of observation were extended to all high risk infants a mortality rate of 4.8 per thousand might be expected.

Funds did not permit the prolongation of the study to enable us to establish unequivocally the benefits of surveillance or to determine which components reduce mortality. But, since January 1975 all infants born in the new County District of Sheffield have been scored and the community health authorities, including the health visitors, have been regularly notified of all high risk infants. In addition since August 1975 a new system has been introduced whereby all infants are examined in the home by a health visitor at the age of 4 weeks. The post perinatal infant mortality rate for 1975 and 1976 is 4.7 per thousand, which is almost exactly the rate expected if surveillance is effective, and is statistically significantly lower than 6.3 per thousand, the post perinatal mortality rate for these years in England and Wales, $P < 0.01$.

We conclude that infants at increased risk of unexpected post perinatal death can be identified at birth. Our data also suggest that post perinatal deaths may be prevented by alerting the primary health care nurses to the surveillance of this group. We have also recently shown that the identification of high risk children can be made more effective by encorporating information on the early development of the child by a multi-stage scoring system. In a small prospective test 71% of unexpected deaths were allocated to the high risk group which had a relative risk of 9.2 (ref. 11). We are currently planning to implement multi-stage scoring.

This study was supported by the Foundation for the Study of Infant Death, and the Public Health Department, Sheffield.

Hypolimnas bolina (L.), a mimic of danaid butterflies, and its model *Euploea core* (Cram.) store cardioactive substances

Hypolimnas bolina is a sexually dimorphic nymphalid butterfly with a west to east distribution from Madagascar to Easter Island, and north to south from Japan to Australasia. To the west the female is monomorphic, mimicking species of the oriental and Australasian danaid genus *Euploea*[1]. Eastwards *H. bolina* is frequently polymorphic and most forms are then non-mimetic. In areas where it resembles *Euploea* the butterfly has usually been designated a Batesian mimic. The supposed model feeds on Asclepiadaceae and Moraceae only, two families of plants of which various species possess emetic, toxic and purgative properties, whereas the foodplants of *Hypolimnas* include examples from eleven families, only a few of which are irritant or toxic[2]. We now report that when the larva of *H bolina* feeds on *Ipomoea batatas*, the butterfly stores cardio-active substances. Dried specimens of this butterfly, reared on *Asystasia gangetica*, a plant which does not contain these substances (Table 1), evoke no reaction on isolated rat heart, but living specimens produce a slight response. This indicates that in addition to material sequestered from foodplants, the butterfly itself secretes some type of cardioactive substance. A loss of intrinsic toxic qualities after death has been demonstrated in almost all aposematic model Lepidoptera[3], whereas stored secondary plant substances can usually be recorded from an analysis of dried material.

Possibly relevant to our findings with *H. bolina* is the fact that this butterfly has several features unusual in classical Batesian mimics: (1) the mimetic pattern has not broken down in Madagascar where the model is lacking; (2) although polymorphic—like many Batesian mimics—several of the forms are non-*Euploea*-like and have no recognised model butterflies flying with them; (3) *H. bolina* is remarkably long-lived, a characteristic usually associated with toxic models rather than innocuous mimics; (4) inheritance of the wing pattern is different from that found in the mimetic papilios[1]. In *H. bolina* there is no genetic linkage between the locus controlling the mimicry and that responsible for the other polymorphic forms[1].

We have investigated the toxicity or pharmacological activity of *H. bolina* and its model *Euploea core*, extracts of the butterflies and their foodplants being tested on the isolated rat and chicken heart (Langendorff preparation[4]) and fed by gavage to pigeons. The insects were bred as described before[1] and their origins are shown in Table 1.

Our results are set out in Tables 1 and 2 and Fig. 1. As Table 1 shows, chicken heart responded to extracts of the model *E. core*, reared either on *Nerium oleander* or three *Asclepias* species, by a reduction in both heart rate and strength of contraction. This suggests that *E. core* stores cardenolides, presumably sequestered from the foodplant[5], although other cardioactive substances may also be present, masked by plant material. But no emetic effects were produced by feeding pigeons with extracts of either fresh or dried adults or pupae (several trials), showing that the butterfly is not such an effective storer of cardiac glycosides as another model, *Danaus plexippus* (ref. 6 and C. A. Dixon, J. M. Erickson, M.R. and D.N.K., in preparation). The situation is reminiscent of that recorded for the African model of the related *Hypolimnas misippus*, *Danaus chrysippus*[7,8], in which sequestration and storage is less effective

Table 1 Effects of adult butterfly extracts on isolated heart

	Foodplant	Sex	No. of experiments	Av. no. of insects extracted per experiment	Av. wt of insects extracted per dose (mg)	Heart tested	% Change in heart rate (mean and range)	% Change in strength of contraction (mean and range)
Euploea core asela Sri Lanka	*Nerium oleander*	Female	6	3.1	86	Chicken	−32.8 (−20, −60)	−26.5 (−11, −66)
		Male	4	2.8	101	Chicken	−16.8 (0, −65)	−13.8 (0, −48)
	Asclepias curassavica	Female	1	3	59	Chicken	−19	−11
	Gomphocarpus fruticosus	Male	1	3	84	Rat	−28	+20
Euploea core amymone Hong Kong	*Nerium oleander*	Female	1	4	73	Chicken	−26	−26
		Male	1	3	58	Rat	−37	+32
	Asclepias curassavica	Male	1	3	191	Rat*	−29	+23
	Gomphocarpus fruticosus	Female	1	2	60	Chicken	−15	−15
		Female	2	3	126	Rat†	−30 (−30)	+21 (+16, +26)
		Male	1	3	191	Rat	−29	+23
	Calotropis procera	Female	1	2	59	Chicken	−21	−16
		Male	2	3	139	Rat	−24.5 (−19, −30)	+18 (+16, +20)
Hypolimnas bolina Sri Lanka, Fiji, Sabah	*Ipomoea batatas*	Female	3	5	89	Rat‡	−42 (−5, −71)	+51 (+20, +66)
	Asystasia gangetica	Female (dried material)	1	5	33	Rat	0	0
		Male (dried material)	1	7	44	Rat	0	0
		Female (fresh material)	1	5	121	Rat	Trace of cardiac activity	—
		Male (fresh material)	1	5	58	Rat	Trace of cardiac activity	—

Euploea extracts were made from live butterflies, *Hypolimnas* extracts from dried material (storage time 2–3 yr) and live material. Extracts from *Hypolimnas* females fed on *Ipomoea*, when injected into the haemocoel of locusts, caused paralysis after 10 min followed by death after 24 h. Neither extracts of dried *Hypolimnas* nor extracts of fresh or dried *Euploea* caused emesis after administration to the pigeon by gavage. Heart rate and strength of contraction were measured for 30 s beginning 10 s after the injection of extract. The control injection effect due to the saline diluent used in mixing extracts is seen in all three figures as a drop in strength almost immediately after injection. Figure 1*a* shows the less common injection artefact of raising the baseline.

* See Fig. 1*b*.

† See Fig. 1*a*.

‡ See Fig. 1*c*.

and more variable, depending not only on the type of foodplant but on other, probably genetic, factors.

There seemed to be no consistent differences between the cardioactivity produced by the two subspecies of the model *E. core asela* and *E. core amymone*, or by either sex, when fed on the same plants.

Hypolimnas bolina (Table 1), when reared on *Ipomoea batatas* (Convolvulaceae), contained cardioactive substances which also reduced heart rate and increased strength of contraction of the rat heart. Similar activity was produced by extracts of the foodplant *Ipomoea* (Table 2), which genus contains an unusually high proportion of aposematic herbivores[9].

Although the concept of mimicry is now firmly established there is still discussion about the limitations of Batesian and Müllerian categories. It has recently been recognised that the role of model and mimic can vary according to local conditions and geographical distribution[7,8,10]. Thus a model can be more or less toxic or distasteful according to the secondary plant substances available in its diet.

Our experiments with captive and wild birds (ref. 1 and unpublished results of M.R.) have shown that *H. bolina* is not a distasteful species for Corvidae, passerines and quails (*Coturnix*), but that *E. core*, in spite of its lack of emetic qualities, is rejected by these captive birds (unpublished results of M.R.). The presence of cardioactive substances in *H. bolina* when it is reared on *I. batatas* indicates that this butterfly is also an opportunistic sequesterer of active secondary plant substances, and can probably acquire other deterrents such as pyrrolizidine alkaloids from *Senecio* (a recorded foodplant) should the opportunity arise. The foliage of *I. batatas* has been suspected of poisoning stock in Arizona and Australia[11,12] and there is a report of a severe outbreak of gastro-enteritis in a Bombay jail traced to this source[13].

In addition to specific glycoresins with purgative activity, *Ipomoea* has been shown to contain indole derivatives (containing the nucleus of lysergic acid) and dendrolasin[14], a sesquiterpine. Any of these toxic substances might be sequestered by *H. bolina* from a particular strain of *I. batatas*.

Hypolimnas is a genus which contains about 30 species, two-thirds of which are mimics of danaids. From our

Fig. 1 On each figure the horizontal line indicates 10 s; extracts were given at the points shown by the arrows. Fluctuations in heart rate and strength of contraction in the first 6–10 s after administration of the extract are injection artefacts and have been ignored in the calculations of results shown in Table 1. *a*, Effect of *Euploea core amymone* (*Gomphocarpus fruticosus*-fed females) extract on the rate and strength of contraction of the isolated rat heart (each vertical trace represents one heart beat). *b*, Effect of *Euploea core amymone* (*A. curassavica*-fed males) extract on the isolated rat heart. *c*, Effect of *Hypolimnas bolina* (*Ipomoea*-fed females) extract on the isolated rat heart.

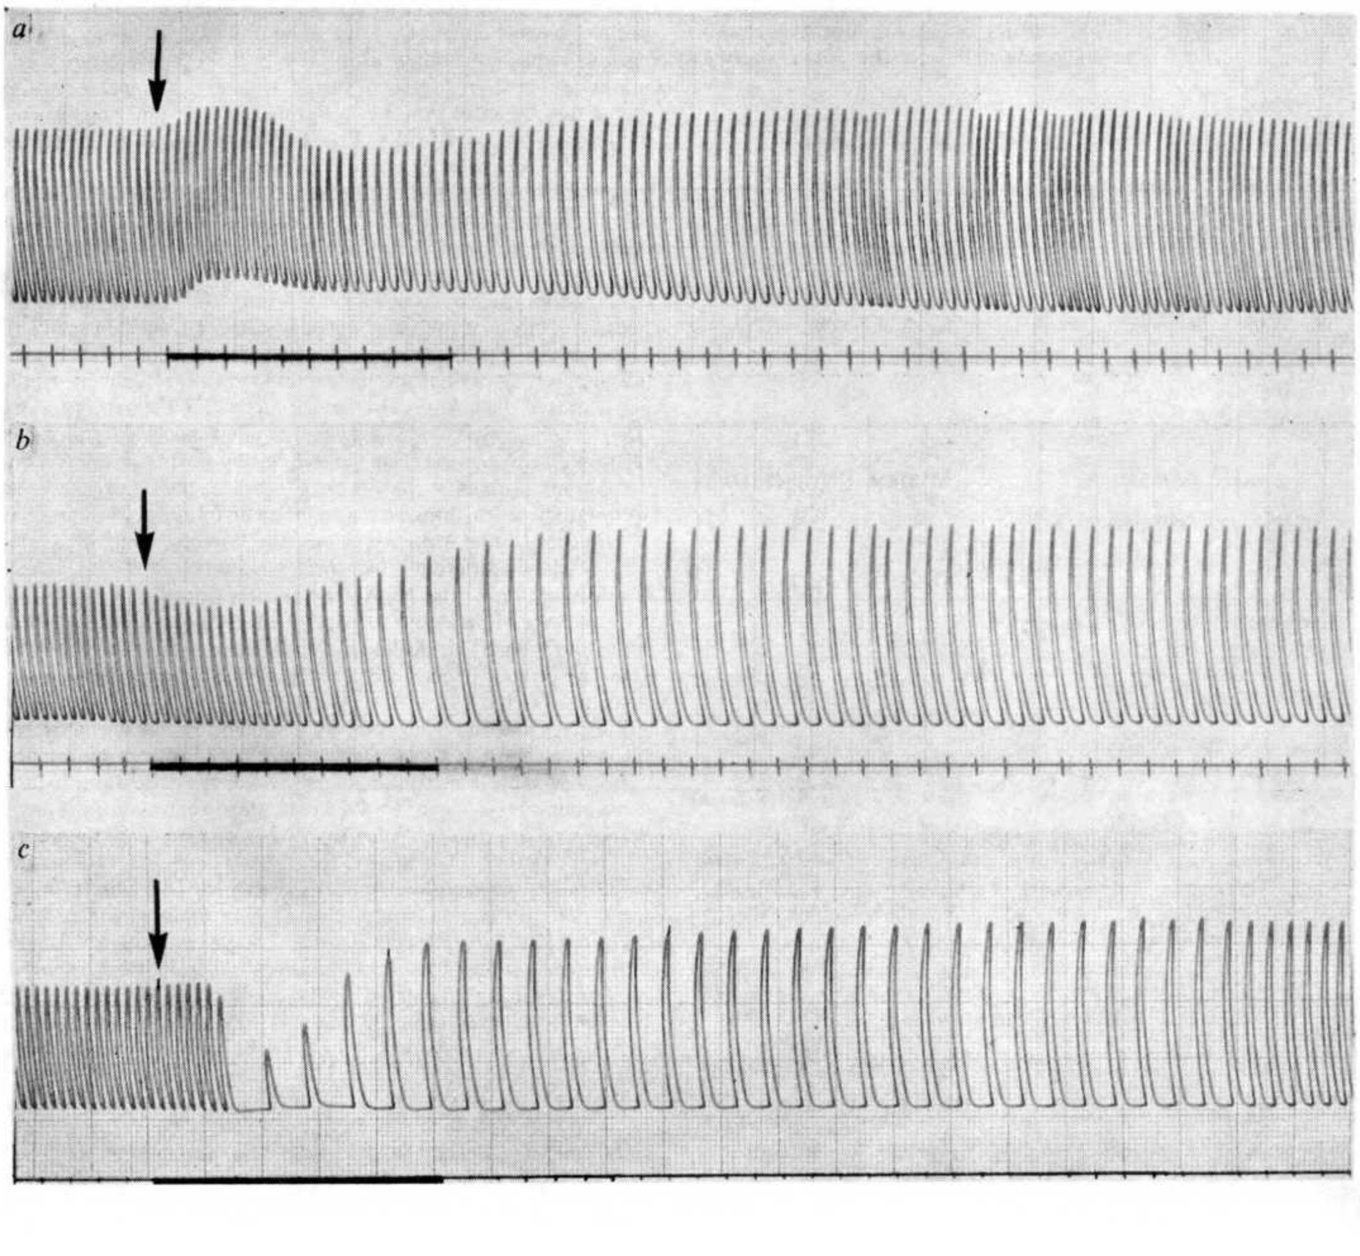

Table 2 Effects of foodplant extracts on the isolated heart and on the pigeon

	No. of experiments	Av. wt of plant extracted per dose (mg)	Heart tested	% Change in heart rate (mean and range)	% Change strength of contraction (mean and range)	Effect of feeding extract of foodplant by gavage*
Ipomoea	3	111	Rat	−47 (−3, −100)	+36 (0, +86)	0
batatas	1	58	Chicken	−15	−8	
Asystasia	1	60	Rat	0	0	ND
gangetica	1	60	Chicken	0	0	
Nerium	1	114	Rat	−16	−41	+++
oleander	1	157	Chicken	+100	+72	
Asclepias	2	115	Rat	−58.5 (−52, −65)	−10 (−5, −15)	+
curassavica	1	160	Chicken	−33	+36	
Gomphocarpus				ND	ND	+++
fruticosus						
Calotropis				ND	ND	++
procera						

Extracts were of foliage, except for *Ipomoea* for which both stems and foliage were extracted. Extracts of *Ipomoea* had no effect on the locust after injection into the haemocoel.

*ND, not done; +++, vomiting within 5 min; ++, within 6–14 min; +, within 15–30 min.

preliminary experiments we draw the tentative conclusion that *H. bolina* has a special type of Müllerian mimicry relationship with *Euploea*, and according to circumstances and the species of foodplant available, either species can play the part of model or mimic and have co-equal 'common warning coloration'. Others[15–17] have drawn attention to the unusual distribution of *H. misippus* and its model, and it seems likely that this species, which at times also feeds on *Ipomoea* (unpublished results of David Smith) demonstrates a similar type of relationship to that of *H. bolina* and *E. core*.

Decay in juvenile hormone biosynthesis by insect corpus allatum after nerve transection

THE ability of the insect corpus allatum (CA) to synthesise and release juvenile hormone (JH) is believed to be controlled by various neural and humoral influences of both stimulatory and inhibitory nature[1]. In last instar *Galleria mellonella*, a CA stimulatory neurohormone (allatotropin) originating in the medial neurosecretory cells of the brain and operating during the early part of the instar has been proposed[2,4]. In the later part of the instar the synthesis and/or release of JH is inhibited by nervous impulses originating in the brain and reaching the CA through nervous connections[2]. A similar nervous inhibition of JH synthesis is thought to operate in adult *Pyrrhocoris apterus*[5] and in the cockroaches *Leucophaea maderae*[6] and *Diploptera punctata*[7], because section of the nervi corporis allati 1 (NCA 1) seems to activate the CA. A neurohormonal factor from the medial neurosecretory cells of the pars intercerebralis which causes the activation of the CA has also been proposed in the orthopterans, *Anacridium aegyptium* and *Locusta migratoria*[8]. In still other Orthoptera, *Schistocerca* sp., the necessity for intact NCA 1 for activation of the CA has been suggested, indicating a direct stimulatory neural influence rather than an inhibitory influence or a humoral stimulation[9,10]. Thus the factors controlling JH biosynthesis in different insect species are not clear. We show here that disruption of the NCA 1 by section during the first gonotrophic cycle of the desert locust *Schistocerca gregaria* results in a rapid and predictable decline in the ability of the CA to synthesise JH. The effect of section of the NCA 1 on JH biosynthesis is detectable within 3 h.

To determine the effect of nerve section on JH biosynthesis, the NCA 1 to each CA was severed at selected times during the first gonotrophic cycle of female locusts. After nerve section, locusts were maintained for up to 4 d in standard rearing conditions[11] before assaying the rate of biosynthesis of JH (C_{16}JH—methyl 10,11-epoxy-3, 7, 11-trimethyl-*trans, trans*-2, 6-dodecadienoate) using our *in vitro* radiochemical procedures[12,13]. Observations were made on glands from locusts during the first gonotrophic cycle (8–13 d after fledging) and changes in the rate of JH biosynthesis of up to several hundredfold have been reported previously during this period[11]. Maximal rates of JH biosynthesis have been observed to occur on day 11 (ref. 11) and the effect of nerve section on biosynthetic rates may be most easily observed at this time.

Figure 1 shows the rates of synthesis of JH during the first gonotrophic cycle for operated locusts (NCA 1 severed) and for sham-operated locusts (NCA 1 touched but not severed) between 1 and 4 d after the operation. The lines join the median values for each day. Differences between median values for the various times after nerve section are small on any given day (on days 9 and 11), and cannot be distinguished in Fig 1. At all times the median JH biosynthetic rate in sham-operated animals was greater than that in operated animals The median values for operated animals were consistently low throughout the experiment and no differences were apparent between animals in which the NCA 1 were severed for various times. The sham-operated values reached a maximum on day 11, in good agreement with results for unoperated normal animals[11]. These results indicate that within 1 d of section of the NCA 1, the CA lost the ability to biosynthesise JH, and did not regain it for at least 4 d.

Because of this rapid loss in CA activity, the JH biosynthetic abilities of CA were determined at 3–6 h intervals during the first 24 h after the operation Locusts 10–11 d after fledging were used because of the high JH biosynthetic rates observed at this time. Figure 2 shows that CA activity again decreased rapidly after nerve section; within 3 h values for operated animals were consistently lower than those for sham-operated animals, and by 6 h, JH biosynthesis by CA of operated animals was low The assay procedure included a 3 h incubation of CA *in vitro* so that the values in Fig. 2 represent the rates of JH biosynthesis during a 3 h interval after the elapsed post-operative period. Thus the values at 3 h, for example, actually represent the rate of JH biosynthesis between 3 and 6 h after the initial operation; similarly, 12 h values represent the rate of biosynthesis between 12 and 15 h after nerve section.

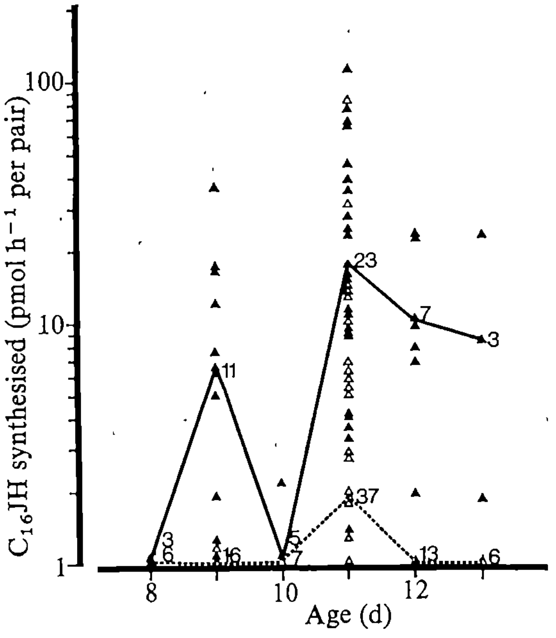

Fig. 1 The rate of synthesis of C_{16}JH by corpora allata during the first gonotrophic cycle of *Schistocerca gregaria* at various times after section of the NCA 1. Values on day 8, 2 d after nerve section, day 9—2 and 3 d after section, day 10, 3 d after section, day 11, 1 and 4 d after section, day 12, 2 d after section, day 13, 3 d after section Each point represents a single determination on an individual pair of glands Δ, Animals in which the NCA 1 was sectioned, ▲, sham-operated animals The dotted line joins the median values of NCA 1-sectioned animals and the solid line joins the median values of sham-operated animals The numbers adjacent to the median values represent the total number of determinations on any given day In every case, the median rates of synthesis in operated animals are lower than the sham-operated animals and never greater than 2 pmol per h per pair The rates of synthesis of C_{16}JH were monitored by incubation of the glands for 3 h in TC 199 (GIBCO, 25 mM HEPES) containing Ficoll (20 mg . ml^{-1}) and methyl ^{14}C-methionine (Amersham–Searle, final specific radioactivity 35–37 mCi mmol^{-1}) After incubation, glands plus medium were extracted with 15 volumes of $CHCl_3$ C_2H_5OH (5·1) after adjustment to *p*H 4 6 and addition of appropriate non-radioactive marker compounds Extracts were analysed by thin layer chromatography (Merck F_{254} silica gel) in ethyl acetate *n*-hexane (25 75) Radioactivity in C_{16}JH was quantified by liquid scintillation spectrometry.

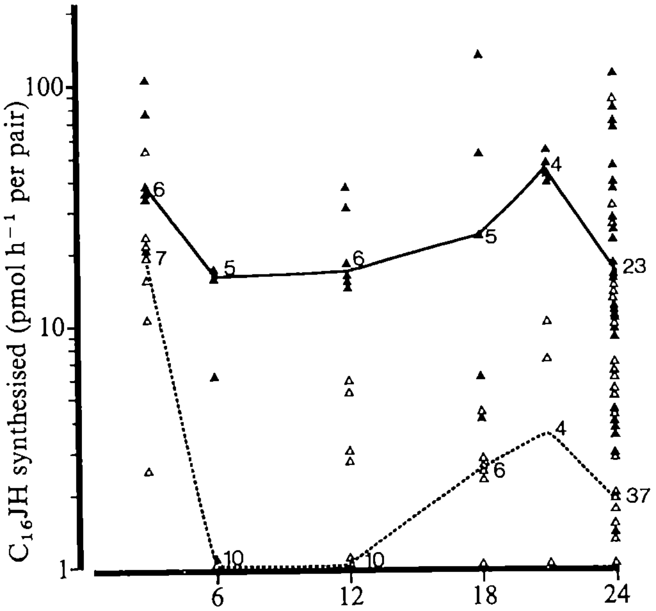

Fig. 2 The rate of synthesis of C_{16}JH by corpora allata on day 11 after fledging at various times after section of the NCA 1 Each point represents a single determination on an individual pair of glands Symbols and methods as for Fig 1 In every case, the median rates of synthesis in operated animals are lower than those of the sham-operated animals The effect of nerve section can be seen within 3 h of the operation and by 6 h, the rate of synthesis has dropped to a low level Section of the NCA 1 results in a rapid decline in C_{16}JH biosynthesis

It is useful to compare the decay in CA activity after nerve section with the time course of release of JH by locust CA *in vitro* (completely denervated) It has been shown that JH is released at a constant rate from isolated CA of *S gregaria* for 3 h *in vitro*[14] and release then declines rapidly, principally in CA with high synthetic activity. Our results *in vivo* confirm these observations because there was a significant decrease in the rate of JH biosynthesis within 6 h of nerve section, that is, 3 h after nerve section *in vivo* + 3 h incubation *in vitro*. CA with low rates of JH release (low activity CA), however, continue to release JH at a constant rate for at least 5 h (ref. 14). These CA *in vitro* have rates of biosynthesis similar to both those CA with high synthetic activity after 3 h *in vitro* and those CA observed *in vitro* after nerve section. This suggests that CA lacking the appropriate 'neural' input synthesise JH at a low but constant rate for some time, whether *in vivo* or *in vitro* Section of the NCA 1 in animals with active CA therefore resulted in a rapid decline in CA activity whereas section of the NCA 1 in animals with CA of low synthetic activity did not significantly alter the rate of JH biosynthesis. There was a large between-animal variation in the rates of biosynthesis in both unoperated locusts[11] and in sham-operated animals (Figs 1 and 2) and we attribute much of this to the difficulty in obtaining completely synchronised populations of animals, when the activity of the CA is changing so rapidly[11]. Because not all of the experimental CA exhibit high activity at any given time, the effect of nerve section on CA activity is probably more pronounced than Figs 1 and 2 indicate.

It may be suggested that section of the NCA 1 damages the CA, thus altering their ability to synthesise JH. To test this possibility, we incubated CA from both operated and sham-operated animals at two times after nerve section, in the presence of the exogenous precursor farnesenic acid. Farnesenic acid has been demonstrated previously to undergo rapid conversion to C_{16}JH through esterification and epoxidation[12,15], and any damage to the cells of the CA presumably would be reflected in an impaired ability to effect these terminal critical steps in JH biosynthesis. Table 1 shows the biosynthetic rates by CA from 11-d locusts 12 and 24 h after section of the NCA 1, incubated in the presence of farnesenic acid. *t* tests on these values at each time revealed that there was no

Table 1 $C_{16}JH$ synthesis *in vitro* in presence of farnesenic acid after section of the NCA 1

Adult age (d)	Time after section of NCA 1 (h)	$C_{16}JH$ Synthesis (pmol per h per pair) Operated	Sham-operated
11	12	Mean 167.9 ± 20.4 Median 171.5 ($n = 10$)	181.1 ± 23.2 183.1 ($n = 8$)
11	24	Mean 95.1 ± 7.62 Median 95.1 ($n = 7$)	121.3 ± 13.0 118.0 ($n = 7$)

Mean values are ± s.e.m; *n*, no. of animals assayed. There is no significant difference between operated and sham-operated values. At 12 h, $P > 0.6$ and at 24 h, $P > 0.05$.

significant difference in JH biosynthesis between operated and sham-operated CA ($P > 0.6$ at 12 h; $P > 0.05$ at 24 h). This demonstrates that section of the NCA 1 does not alter the ability of the CA to effect the final two stages in JH biosynthesis. In addition, these results suggest that the stimulatory or sustaining factor(s) arriving at the CA through the NCA 1 do not exert their effects by altering the activities of the two terminal enzymic stages. It has been suggested that rate limitation in JH biosynthesis does not occur at the final two stages in *S. gregaria*[15], and our results support this suggestion.

Our results show that the presence of intact NCA 1 is necessary for the continued biosynthesis of JH by active CA in this species and provide a possible explanation for the difficulties encountered by some authors when attempting to promote sexual maturation or the expression of juvenile characters through the implantation of homologous CA (refs 16–18). The CA from adults of certain other species seem to respond differently. For example, CA from female *Periplaneta americana* take more than 36 h to reduce their rate of incorporation of ^{14}C-methionine into $C_{16}JH$ when isolated in chemically-defined culture medium[20], and there is physiological evidence that these glands may retain significant levels of synthetic activity for several weeks when transplanted to larval *Rhodnius prolixus*[21]. These other CA may be less acutely dependent upon the integrity of their nervous connection to the brain than those of *S. gregaria*, and in some cases may be able to respond independently to trophic humoral factors if these are present.

Our results suggest that if a stimulatory or sustaining factor regulates JH biosynthesis in adult *S. gregaria*, this factor does not normally operate by a humoral pathway. Massive electrical stimulation of the pars intercerebralis of *L. migratoria* and *A. aegyptium* has been reported to result in activation of denervated inactive CA (ref. 8). We suggest that although massive release of neurosecretory material may result in activation of the CA by a humoral pathway in experimental conditions, this is not the normal pathway in *Schistocerca*. Rather the factor must reach the CA by the nervous tracts. Other authors have shown that electrical stimulation of the brain in *S. gregaria* also results in activation of *intact* CA (ref. 19). Thus activation may occur by conventional nervous pathways as well. It is not known if the 'allatotropic' factor is the product of neurosecretory cells or conventional neurones or if both types of products are involved in the activation of the CA. With regard to the latter possibility, conventional neurones may regulate the release of neurosecretory products within the CA. Such a mechanism may regulate the release of egg-laying hormone (a neurosecretion) in *Aplysia*[22,23].

Sex hormone of *Dictyostelium discoideum* is volatile

THE macrocyst pathway of development represents the sexual cycle of the cellular slime moulds[1–4]. O'Day and Lewis[5] have shown that the sexual interaction between opposite mating types of *Dictyostelium discoideum* is mediated by a low molecular weight, diffusible hormone. They also showed that only one mating-type strain (NC-4) was a secretor of the sexual hormone while the opposite strain (V-12) was a responder (that is, formed macrocysts). This sexual interaction was verified by MacHac and Bonner[6] and was later shown to exist in another species, *D. purpureum*[7]. In our attempts to characterise the sexual system of *D. discoideum*, our results have revealed that the sexual hormone of this species is volatile.

Figure 1 depicts the construction of the diffusion chamber and outlines the culture methods used in this study. The stock cultures of the mating-type strains (NC-4 and V-12)

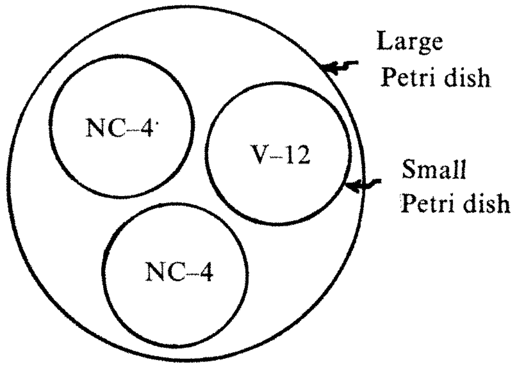

Fig. 1 Diagram of the diffusion chamber with an example of the most successful inducing situation. Small Falcon plastic Petri dishes (30 × 10 mm) containing 4.0 ml 0.1% L-P agar (0.1% Difco peptone, 0.1% Difco lactose, 1.5% Difco agar) were inoculated with 0.5–1.0 ml suspension of *E. coli* B/r and spores (1–2.5 × 10^4 spores) of one mating-type strain of *D. discoideum*, Three of these small dishes were placed uncovered in a large Fisher plastic Petri dish (100 × 15 mm) which was then covered and sealed with tape (masking tape or 3M vinyl electrical tape). The sealed plates were placed in light-tight metal canisters and stored for two weeks at 23 ± 1 °C before observation.

Table 1 Macrocyst formation in diffusion chamber cultures

Experimental situation	No. of chambers set up	No. of small plates with pre-cyst clumps*		No. of small plates with mature macrocysts*	
		V-12	NC-4	V-12	NC-4
Two NC-4; one V-12	42	30/42	0/84	6/42	0/84
Two V-12; one NC-4	20	5/40	0/20	0/40	0/20
Two d-H_2O; one V-12	10	0/10	NA	0/10	NA
Three NC-4	20	NA	0/60	NA	0/60
Three V-12	20	0/60	NA	0/60	NA

*Macrocyst formation involves an initial aggregation of cells to form discrete, tight cell clumps (pre-cyst clumps) which, in appropriate conditions, form dormant structures possessing three cell walls (mature macrocyst). Data are expressed as ratios of the total number of small plates with pre-cyst clumps or mature macrocysts to total number of small plates used for that strain.

used to inoculate the small Petri dishes were maintained on *Escherichia coli* strain B/r on 0.1% L-P agar at 22–24 °C in the presence of light[8]. The three small plates of the diffusion chamber were inoculated in the following combinations: two NC-4 and one V-12; two V-12 and one NC-4; two distilled water and one V-12; three NC-4; three V-12. After two weeks the small plates of each chamber were examined for the presence of macrocysts.

The results of these experiments are summarised in Table 1. Pre-cyst cell clumps and mature macrocysts were only observed in cultures of V-12. Furthermore, these structures were only observed when at least one NC-4 culture was present in the diffusion chamber, whereas mature macrocysts were only observed when two NC-4 cultures were present. In other experiments, seven of the small Petri dishes (six NC-4; one V-12) were placed in a very large, sealed, plastic Petri dish (150×20 mm) in an attempt to increase the level of macrocyst formation. Only a low level of macrocyst formation by V-12, however, was observed, possibly due to the large air space in such containers. The fact that only V-12 cultures contained macrocysts argues that cell migration from one small dish to another did not occur. As an additional control, however, in several experiments a 'moat' of sterile, distilled water was placed around the base of the small Petri dish containing the V-12 culture. After the two-week period, the contents of the moat were examined by phase contrast microscopy. Amoebae were never observed in this fluid, re-emphasising that cellular migration between plates did not occur.

In a different but related series of experiments, ten mixed mating-type cultures of NC-4 and V-12 were left unsealed, whereas ten were sealed. In these experiments, the sealed dishes routinely showed 500 or more macrocysts per plate, whereas the unsealed cultures had 50–100 or fewer.

The results thus reveal that the sexual hormone of *D. discoideum* is volatile. This organism, however, is not unique, since volatile sex hormones are produced by many other eukaryotic microbes[9]. In addition, volatile molecules may play a role in other aspects of slime mould development such as in the spacing of fruiting bodies, in the formation of microcysts and in homothallism[10,11]. The data are also consistent with the concept that macrocyst formation is at least a two-step phenomenon. Since pre-cyst clumps only formed in cultures which had a ratio of one NC-4 to two V-12, whereas mature macrocysts were formed by V-12 when two NC-4 cultures were present, it is likely that a low level of hormone may induce pre-cyst formation, while a higher level of this hormone or, possibly, a second volatile molecule may be required for events to proceed past this point.

Finally, the fact that the aggregation-inducing factor for sexual interaction is volatile at 23±1 °C, whereas cyclic AMP is not, reveals that the events of cell aggregation in these two alternative developmental events are different. Presently we are continuing our attempts to identify the sexual hormone of *D. discoideum*.

Modification of circadian flight activity in the mosquito *Anopheles gambiae* after insemination

THE flight activity of female *Anopheles gambiae* Giles, recorded in the laboratory, follows a bimodal cycle[1]. In LD12:12 (alternating 12 h light:12 h dark) the first peak comes shortly after light-off and there is a secondary phase of activity which reaches its maximum in the middle or latter part of the dark phase. This secondary activity occurs at the time when host seeking and biting take place in the wild[2]; the initial peak corresponds with the time of egress of mosquitoes from their daytime resting places and, in particular, in virgin females, with the time of mating[3]. In normal conditions, *A. gambiae* females are inseminated only once in their lifetime[4,5], and usually not before they are 2–3 d old (ref. 3). We show here that, after insemination, the first peak of activity is greatly reduced and the secondary phase of activity is enhanced. This switch in activity is likely to represent a change from mating to host seeking behaviour.

Pala strain female mosquitoes, were sugar-fed and reared at 26 °C in an LD12:12 regime. Males and females were separated following emergence. When 3–4 d old, half the females were placed in a cage for 24 h with twice the number of males; the insemination rate was approximately 90%. The flight activity of similar numbers of individual virgin and mated females was then recorded for a week, using the acoustic actograph technique[6,7]. The experiments were first carried out in an LD12:12 regime with a sharp change from light to dark and vice versa, and then repeated using an electronically produced artificial dawn and dusk[3] with the transition lasting approximately 75 min. After each experiment, survivors were dissected and spermathecae examined.

Figure 1 shows the mean flight activity of virgin and inseminated females 6 d after emergence, that is, in the case of the

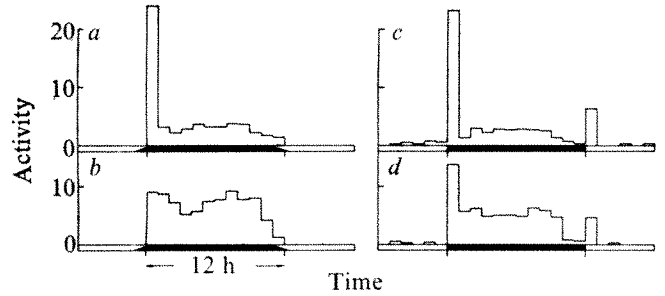

Fig. 1 Flight activity (mean score per h) of sugar-fed *A. gambiae* females in LD12:12. *a*, *b*, With an artificial dawn and dusk: *a*, virgins ($n = 29$) and *b*, inseminated ($n = 28$). *c*, *d*, With sharp light-on and light-off: *c*, virgins ($n = 42$) and *d*, inseminated ($n = 25$).

mated females, 24 h after the end of their confinement with the males. In both types of regime, inseminated females show a significant decrease in amount of activity in the first hour of the dark period (t test, $P < 0.01$ in both cases) and an increase in the secondary activity (t test, $P < 0.02$ in both cases). The net effect is an increase of 30–50% in the total activity during the dark phase. The same pattern was observed throughout the experiment. The difference in activity between virgin and inseminated females is more immediately apparent in dawn and dusk conditions. Possibly the peak shown by the inseminated females in Fig. 1*d* is partly a response to the sharp change at light-off; the peak at light-on has already been shown to be a response to such a sharp change[1].

Craig and his co-workers[8,9] have demonstrated that in *Aedes aegypti* and a number of other mosquitoes, the female is rendered refractory to further insemination through the action of the male accessory gland secretion, which is transferred to the female in the seminal fluid. These secretions may also affect the female by stimulating oviposition, modifying biting behaviour, increasing the rate of digestion of blood meals and possibly enhancing longevity[10,11]. It seems probable that the behavioural changes we have observed are a consequence of the transference of accessory gland substance. The switch in behaviour could be particularly important in a species such as *A. gambiae* in which mating and feeding may take place at entirely different sites.

2,4-D plasmids and persistence

According to the UN Food and Agricultural Organisation production year book of 1974, 27×10^6 kg of the herbicide 2,4-dichlorophenoxyacetic acid (2,4-D) were consumed in 1973, making this the most extensively used of all pesticides. One desirable characteristic of 2,4-D, apart from its efficacy as a herbicide, is its lack of persistence in the environment[1], due to degradation by a variety of microorganisms. We have argued that in view of the isolation of plasmids encoding the degradation of naturally occurring aliphatic and aromatic compounds[2], there exists a class of plasmids which specifically encode the degradation of many man-made derivatives of these compounds, in this instance 2,4-D. Using segregation and transfer analyses we have demonstrated that a plasmid or plasmids is involved in 2,4-D degradation. Clearly bacteria have evolved which can degrade many different pesticides; our results indicate that plasmids may have an important role in this evolution.

Initial attempts to study 2,4-D degrading ability in soil bacteria were hampered by the marked instability of this character in many of our isolates. We have isolated a strain of *Pseudomonas* (JMP116) that degrades 2,4-D and retains this characteristic even after subculture in the absence of 2,4-D. Degradation of 2,4-D by JMP116 was detected by acid production in Loos' media[3], disappearance of the 283-nm absorption peak[4] and growth on 2,4-D as a sole source of carbon and energy. Since JMP116 does not degrade phenoxyacetic acid, we have concluded that this pathway is specific for 2,4-D.

In view of the segregation of 2,4-D negative clones by certain of our isolates we examined the possibility that these genes are plasmid borne. We have found that the wild-type JMP116 is readily cured of its 2,4-D degrading ability of mitomycin C. After JMP116 at 10^7 colony-forming units (CFU) per ml was inoculated into PYE broth containing 0.1 μg ml^{-1} mitomycin C and grown at 32 °C with aeration for 18 h, 40–60% of the clones re-isolated on PYE were cured of 2,4-D degrading ability. Control cultures without mitomycin C show < 1% spontaneous loss of this character. Since mitomycin C can act as a mutagen, especially in strains which are sensitive to the antibiotic, we tested one cured isolate (JMP119) for back mutation to the wild type, 2,4-D degrading phenotype. This cured strain does not revert to wild type at a detectable level.

Segregation and curing are characteristics of plasmid genes[5]. For many plasmids it is possible to isolate plasmid-specific bacteriophage[6]. PR11 is a plasmid-specific bacteriophage that formed plaques on strains harbouring RP1, a pseudomonas R plasmid with an exceptionally wide host range[7]. This bacteriophage also plaques on JMP116, but not on JMP119 (a JMP116 derivative cured of its ability to degrade 2,4-D). It is likely that JMP116 harbours a conjugative plasmid related to RP1 that encodes 2,4-D degradation. This has been confirmed by an intrastrain mating between JMP116 and a nalidixic acid resistant mutant of JMP119. The results (Table 1) show that the plasmid is transferred with a frequency of 5×10^{-2} per donor cell in an overnight mating, and there is a 100% correlation between the acquisition of the plasmid and the ability to degrade 2,4-D. Although failure to separate the conjugative phenotype from the 2,4-D degrading phenotype in either curing (unpublished data) or transfer experiments suggests that the 2,4-D degrading ability is encoded by a conjugative plasmid, it must be recognised that more than one plasmid may be involved—for instance a non-conjugative plasmid, specifying the degradative pathway, being mobilised by a conjugative plasmid. Information on the actual number of plasmid species involved in 2,4-D degradation is being sought by the isolation and characterisation of plasmid DNAs from JMP116 and JMP119.

Torstensson *et al.*[8] have reported that the continued application of 2,4-D results in a progressive decrease in its persistence. They point out that the adaption hypothesis does not explain why this increased ability to degrade 2,4-D persists from one year to the next. Our results show that the presence of pesticide degrading plasmids have an important role in the lack of persistence of 2,4-D. This report of a pesticide degrading plasmid and its relationship

Table 1 The relationship between the inheritance of a conjugative plasmid and the ability to degrade 2,4-D

Possible phenotypes	No. of colonies
Ped$^+$ φ^r	0
Ped$^+$ φ^s	52
Ped$^-$ φ^r	1,000
Ped$^-$ φ^s	0

Ped$^{+/-}$, ability/inability to degrade 2,4-D. $\varphi^{r/s}$, Resistance/sensitivity to the plasmid specific bacteriophage PR11. Intrastrain mating between JMP116 (*Ped*$^+$) and a nalidixic acid-resistant mutant of JMP119 (*Nal*^{r} *Ped*$^-$). Exponential (about 1×10^9 CFU ml^{-1}) cultures of the donor (JMP116) and the recipient (JMP119 *Nal*^{r}) were diluted one-tenth in PYE broth, mixed in equal volumes and incubated without aeration at 32 °C overnight) (18 h). The recipient was re-isolated on PYE agar containing 20 µg ml^{-1} nalidixic acid. The re-isolated recipient clones were tested for their susceptibility to the plasmid-specific bacteriophage PR11 and ability to degrade 2,4-D in Loos' media[3].

to RP1 raises a number of important questions. How widespread are pesticide degrading plasmids and to what extent do they contribute to the degradation of the myriad of man-made pesticides in use today? Are pesticide-degrading plasmids analogous to antibiotic-resistant plasmids in that the application of the pesticides elicits an epidemic spread of the plasmid through the soil microbial population?

We thank Dr I. C. MacRae for valuable comments and J. Appleton for technical assistance. This project is supported by grant D2 75/15203 from the Australian Research Grants Commission and P.R.F. holds a Postgraduate Award from the Australian Government.

An antiviral substance extracted from *Streptococcus faecalis*

ALTHOUGH there are a number of reports on virus-inhibiting substances, knowledge of those of bacterial origin is rather limited[1–6]. Horsfall and co-workers[7,8] reported that polysaccharides of *Klebsiella pneumoniae* suppressed multiplication of pneumonia virus of mouse *in vivo* and of mumps *in ovo*. Carver *et al.*[9–11] described virus-inhibiting factor(s) which they isolated from different species of bacteria belonging to both Gram-positive and Gram-negative groups. We report here that a substance or substances extracted from *Streptococcus faecalis* inhibited proliferation of certain human pathogenic viruses *in vitro* and *in vivo*.

S. faecalis organisms cultivated in VF bouillon supplemented with 1% glucose and 0.04% cystine were washed and sonicated (20 KHz, 30 min). Supernatant fluid obtained by a centrifugation (12,000*g*, 30 min) was the crude extract; the protein content was determined by the method of Lowry *et al.*[12]. Test virus was usually herpes simplex virus type 1 (HSV-1) propagated in HeLa-S$_3$ cell cultures, and in addition adenovirus type 12 (Ad-12) grown in KB cells.

The HSV suspension and the extract were simultaneously introduced into HeLa monolayer cultures in bottles and incubated at 37 °C for 1 h to allow complete cell–virus adsorption. After removing the excess fluid, overlay medium consisting of methylcellulose (0.5%), calf serum (3%) and kanamycin (60 µg ml^{-1}) in Eagle's minimum essential medium was added. Following incubation at 37 °C for 4 d, the cultures were stained with 1% crystal violet in ethanol. Numbers of plaques thus formed were significantly reduced than those in control cultures added with 0.01 M phosphate-buffered saline (PBS, *p*H 7.0) (ref. 13) in place of the bacterial extract.

The crude extract was subjected to salting out by ammonium sulphate and to acetone treatment, then gel filtration with Sephadex G-100. Particular fractions were comparatively effective in the plaque-inhibiting capacity; typical examples are shown in Fig. 1.

The antiviral substance (AVS) also exhibited an *in vivo* activity. AVS and HSV-1 were simultaneously injected into mice intraperitoneally (i.p.) and mortality ratios of AVS-treated mice were significantly lower than those of control mice given virus alone (Table 1).

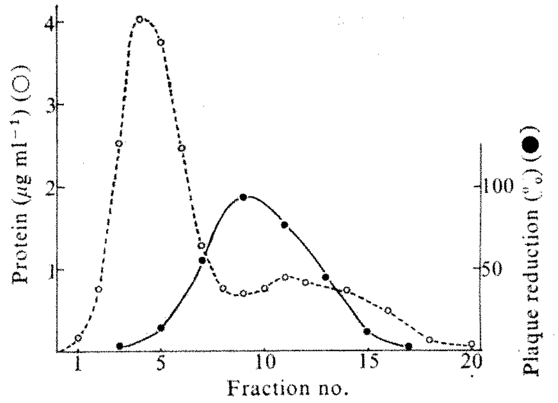

Fig. 1 Profile of Sephadex G-100 gel filtration of an ammonium sulphate precipitate of *Streptococcus faecalis* extract. The bacterial extract was prepared by the procedures indicated in text and adjusted to contain 15 mg ml^{-1} protein by addition of 0.01 M PBS (*p*H 7.0). Ammonium sulphate was then added to 70% saturation and stirred for 30 min at 5 °C. After a centrifugation at 15,000*g* for 30 min, the supernatant was brought to 90% saturation of $(NH_4)_2SO_4$ and stirred for 30 min at 5 °C. The precipitate collected by centrifugation (15,000*g*, 30 min) was dissolved in PBS and dialysed against PBS for 24 h at 5 °C. The non-dialytic fluid was adjusted to contain 8 mg ml^{-1} protein with PBS and gently added with acetone to 40% concentration, which was placed at −10 °C for 20 min. Following a centrifugation (10,000*g*, 30 min), acetone was added to the supernatant to a final concentration of 45% and again placed at −10 °C for 20 min. The precipitate collected by centrifugation (10,000*g*, 30 min) was then dissolved in PBS and dialysed against PBS at 5 °C for 24 h. After the non-dialytic fluid was adjusted to contain 40 mg ml^{-1} protein with PBS, the solution (5 ml) was charged on a Sephadex G-100 column (26 × 700 mm, Pharmacia, previously equilibrated with PBS) and eluted with PBS. Fractions (6 ml each) were collected and each of them was adjusted to contain 800 µg ml^{-1} protein. One-tenth ml each of the samples and 0.1 ml of HSV-1 suspension (adjusted to contain 100 PFU) were simultaneously introduced into HeLa cell monolayer cultures to determine plaque titres.

Similar activity was seen in experiments using suckling hamsters infected with Ad-12 virus. Development of virus-induced tumours was suppressed by administration of AVS. The effect was unequivocal when the AVS was given simultaneously with the virus, but the same substance given 15 d after virus inoculation was much less active (Table 2).

AVS (300–1,000 µg protein per ml) had no direct effect on the infectivity of viruses suspended in culture medium or PBS, and showed no acute toxicity to HeLa cells (at least as determined by morphology under an ordinary light microscope and proliferation capacity in bottles). Injection of AVS i.p. into 3-week-old white mice (320 μg as protein per mouse once a day for 10 days) brought about no loss of body weight, compared with control untreated mice. The antiviral activity resisted heating at 95 °C for 5 min or treatment with RNase or lipase, while it was completely lost or significantly reduced by treatment with proteolytic enzymes such as pronase or trypsin. The AVS was non-dialytic. These data suggest that the active principle is a protein.

AVS apparently lacked activity as an interferon stimulus. Mice, aged 3 weeks, were injected i.p. with AVS (60–1,500 μg protein in 0.4 ml PBS, per mouse). Plasma was taken after 3, 6 and 24 h and interferon titres were determined by the method of Younger *et al.*[14] using vesicular stomatitis virus (VSV) and mouse L cells. No interferon induction was noted in any of the test systems. We also found that the VSV-susceptibility of L cells pretreated with AVS was practically the same as that of control untreated cells; no difference of VSV titres was noted between these two cellular systems.

Table 1 Curative effect of AVS on HSV-1 infection in mice

	Mortality ratio of mice		
Group of mice	Experiment I	Experiment II	Experiment III*
AVS-treated	5/30 (17)†	5/23 (22)	14/85 (16)
Control	24/30 (80)	19/24 (79)	66/85 (78)

Three-week-old male mice (ddY-F strain) were each injected with HSV-1 i.p. (2,000 plaque-forming units each) and AVS (320 μg protein) simultaneously. Mice in control groups received the same virus alone. Observation periods ended at 14 d after the injection. Differences of mortality ratios between the AVS-administered and control groups are significant at the confidence level of 95%.

*Summary of 11 separate experiments carried out in the same way.

†Numerator indicates number of mice which died showing typical signs of HSV-1 infection, and denominator indicates number of mice inoculated; figure in parenthesis indicates percentage.

Some of the mechanism(s) underlying the phenomena were investigated as follows. The HeLa cell monolayer cultures were given HSV-1 and AVS simultaneously. After being incubated at 37 °C for 1 h, the viral titres of fluid phase were determined. As shown in Fig. 2, the amounts of virus which remained unadsorbed in the fluid of AVS-administered cultures were significantly higher than those of the same virus present in the fluid of control cultures receiving PBS in place of the AVS. It was also noted that the amounts of unadsorbed virus were almost constant regardless of the titres of original virus inocula, both in the AVS-administered and control cultures. It seemed that the AVS affected the virus at the stage of adsorption on to host cells.

Extracts were prepared from other kinds of bacteria and tested for virus-inhibiting capacity as above. In all 19 strains of organism of 17 species, including *S. lactis, Lactobacillus acidophilus, L. casei, Bifidobacterium bifidum, Escherichia coli* and *Proteus vulgaris* were examined. None of these samples was superior to the AVS from *S. faecalis* in the antiviral effects. It therefore seems that the virus-inhibiting activity described here may be species-specific.

Table 2 Inhibitory effect of AVS on development of tumours induced by Ad-12

Inoculum*	Tumour incidence (%)	P§
Experiment I		
Ad-12† plus AVS‡ simultaneously	9/19 (47.3)	< 0.01
Ad-12 plus AVS 15 days later	17/20 (85.0)	> 0.2
Ad-12 alone	19/20 (95.0)	
Experiment II		
Ad-12 plus AVS simultaneously	4/11 (36.4)	< 0.05
Ad-12 plus AVS 15 days later	10/11 (90.9)	> 0.2
Ad-12 alone	11/12 (91.7)	

*Inoculated subcutaneously in the back of 1-day-old hamsters.

†5×10^6 $TCID_{50}$ (tissue culture infecting dose) in 0.05 ml; Huie strain grown in KB cells.

‡0.265 mg protein in 0.05 ml.

§Calculated by the χ^2 test.

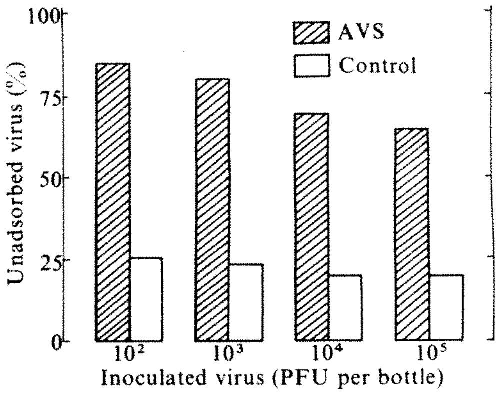

Fig. 2 Amounts of HSV-1 remaining unadsorbed in the fluid phase of HeLa-S_3 monolayer cultures receiving simultaneously virus plus AVS or virus plus PBS. HSV-1 (titres as indicated in abscissa) and AVS (160 μg protein) were simultaneously introduced on to HeLa monolayer cultures in bottles. Control cultures received the same virus plus PBS instead of the AVS. After incubation at 37 °C for 1 h, excess fluid was taken and assayed for the plaque titres which were taken to indicate amounts of virus unadsorbed. PFU, plaque-forming units.

An immunological basis for inhibition of transformation of human lymphocytes by EB virus

IT IS well known that Epstein–Barr virus (EBV) transforms human lymphocytes *in vitro*, and lymphoblastoid cell lines are established[1]. Macrophages enhance transformation by EBV *in vitro*[2] but may not be essential[3]. Inhibition of transformation by EBV *in vitro* has also been reported, and was first observed when lymphocytes from an adult donor with antibody to EBV were infected with EBV and co-cultivated with autochthonous fibroblasts derived from skin[4]. Fibroblasts of foetal origin did not have this inhibitory effect. Further studies established the principle that co-cultivation of EBV-infected lymphocytes with autochthonous or allogeneic fibroblasts of adult but not foetal origin, was associated with inhibition of transformation by EBV (ref. 5). This report presents evidence that this type of inhibition of transformation by EBV is specifically mediated by mononuclear cell preparations from donors previously infected with EBV. An immunological basis is highly probable.

The major characteristics of the experimental system for studying inhibition of transformation by EBV are noted briefly. First, inhibition is defined as the failure of non-adherent lymphocytes to aggregate and proliferate yet still remain infected and viable. Second, inhibition has not been shown to be due to a factor released by adult fibroblasts. Third, inactivation of the inoculated EBV is not the cause of inhibition because an EBV-associated nuclear antigen (EBNA) is demonstrable in the inhibited lymphocytes for several weeks[5]. Fourth, the inhibition is reversible up to at least four weeks after inoculation of EBV by simply adding phytohaemagglutinin to the cultures[6] or by removing the non-adherent lymphocytes from the adult fibroblasts and transferring them to a clean tissue culture vessel[5,6]. Finally, reversal of inhibition results in proliferation of the EBV-infected cells within a few days, and typical lymphoblastoid cell lines emerge[5]. The proliferation of cell lines already transformed by EBV is not inhibited in the presence of adult fibroblasts[5].

In a series of experiments, inhibition of transformation by EBV was consistently recorded when EBV-infected lymphocytes of three donors with antibody to EBV were co-cultivated with fibroblasts from skin of two adult donors, but not when they were co-cultivated with fibroblasts derived from four different foetuses. In contrast, inhibition of transformation by EBV was not demonstrated with lymphocytes from a donor without antibody to EBV. This observation prompted a detailed investigation of the relationship between inhibition of transformation by EBV *in vitro* and the previous history of EBV infection of the lymphocyte donor.

The methods used in this work have been described in detail[1,7]. In essence, mononuclear cell populations were prepared from peripheral blood and the adherent cells removed by incubation in medium containing autochthonous serum in plastic Petri dishes. The non-adherent mononuclear cell population (mainly lymphocytes) was infected with filtered EBV of the QIMR–WIL strain and cultured in microtitre plates. Appropriate fibroblast cultures were usually prepared on the previous day. The cultures (at least six replicates) were maintained in medium RPMI 1640 containing 16% inactivated foetal calf serum and observed microscopically for evidence of transformation for at least 4 weeks, although transformation was usually evident in 7 d.

The results of investigations on 14 donors (10 males and 4 females, aged 5–46 yr) were quite clearcut. Non-adherent lymphocytes from each donor, whether with or without antibody to EBV, were uniformly transformed in the usual manner by EBV when cultivated alone or with foetal fibroblasts. A strikingly different pattern occurred in the presence of adult fibroblasts; transformation occurred uniformly with lymphocytes from all eight donors (six adults and two children) without antibody to EBV but with none of the lymphocyte samples from six donors (five adults and one child) with antibody to EBV. In addition, lymphocytes from four umbilical cord blood samples transformed as usual on adult fibroblasts.

In the work reported here, the lymphocyte concentration was 0.5×10^6 ml^{-1} and the multiplicity of EBV infection (MOI) 0.1 TD_{50} per cell. Inhibition was also observed with a MOI of 15 and a cell concentration ranging from 10^5–10^6 ml^{-1}, showing that the phenomenon was not dependent on the dose of virus or the cell concentration. Two experiments were carried out in a different manner. Non-adherent lymphocytes from donors without previous EBV infection (adult and cord) were infected with EBV, mixed with uninfected lymphocytes from donors with previous EBV infection, and co-cultivated with adult fibroblasts. In these conditions, viral transformation was inhibited as described above, confirming that inhibition of transformation is dependent on the presence of lymphocytes from EBV-immune donors.

The effect of previous EBV infection on the role of adult fibroblasts in the inhibition of EBV transformation was also studied. The results, summarised in Table 1, showed that inhibition was dependent on previous EBV infection of the donor of the lymphocytes but not of the donor of the adult fibroblasts.

From the present results it now seems likely that an immunological system capable of inhibiting transformation of lymphocytes by EBV is inherent in the mononuclear cells from persons with previous EBV infection. Detection of this inhibition is so far dependent on particular culture conditions, and the role of fibroblasts of adult origin seems to be simply to provide these conditions. Failure of non-adherent mononuclear cells to inhibit transformation when cultivated alone or in the presence of fibroblasts of foetal origin may be due to unsuitable culture conditions or to interference by other cellular factors. The mechanism of inhibition is unknown but it may well involve a complex interaction of various immunological components. These include the expression of EBV antigens on infected target cells, the particular EBV-specific immunological effector system involved, the survival and activity of the components of the effector system in various culture conditions, and the influence of various mitogenic factors. Obvious possibilities are that the inhibition involves T lymphocytes, antibody, or antibody-mediated cellular immunity, acting at the surface of the EBV-infected cells to modulate their behaviour. These aspects are being examined.

Table 1 Effect of previous EBV infection on role of fibroblasts during inhibition of EBV transformation

*NT, Not tested.

Inhibition of transformation by EBV without death of the target cells contrasts with the cytotoxity for EBV-infected target cells of selected lymphocyte populations from patients with acute infectious mononucleosis[8–9]. Lymphocytes from persons with longstanding EBV infections were not cytotoxic in those two systems. The specificity of inhibition of transformation contrasts also with the nonspecific inhibition by human lymphocytes of EBV lymphoblastoid cell lines[10–12], providing further support for the view that inhibition of EBV transformation acts at a point before the process is complete.

The manner in which EBV persists following infectious mononucleosis is of considerable interest. It has been suggested that cells transformed by EBV persist in the body probably under immunological control[13], or that the EBV genome may persist in cells in an incompletely expressed form[14]. The present studies of inhibition of transformation bear on this particular problem as well as on wider questions of viral latency, especially with herpesviruses.

Intermittent exposure to fluorescent light extends lifespan of human diploid fibroblasts in culture

SHORT exposure (3 or 4 h) to fluorescent light one to three times weekly enhances the proliferation rate of human diploid fibroblasts in culture[1]. This proliferative response is reversible and is mediated through the culture medium, Dulbecco Vogt's supplemented with 10% foetal bovine serum. Conceivably, this increase in proliferation rate might also influence the lifespan of human diploid fibroblasts, which undergo a limited number of population doublings (PDs) in culture[2]. To evaluate the long term effects of repeated light exposure on lifespan, three lines of human fibroblasts originating from adult skin (HU-274), a mince of whole foetus (HU-278), and foetal lung (WI-38), were assayed in quantitative experiments to determine the lifespan measured as cumulative cell number and total PDs

Irrespective of the PD level of the cells at the beginning of the experiment, repeated exposure (3 h) to cool white fluorescent light (6 to 9 W m^{-2}) three times weekly, reproducibly extended the lifespan. This extension was reflected by an increase in the total number of PDs, cumulative increase in cell number, and duration of cell survival and growth (Figs 1–3). Cessation of growth was indicated by a decrease in cell number from inoculum size after 2 weeks' incubation. The cells of both foetal lines, WI-38 and HU-278, which before this experiment had undergone 44 or more PDs and had been exposed to room fluorescent lights during routine handling, showed a 19–21% increase in total PDs (Table 1). In contrast, the cells of adult origin, HU-274, which had never been exposed to light of wavelength less than 500 nm during the initial seven PDs in culture showed a 70–98% increase in total PDs. The unexposed cells of line HU-274 underwent a total of 20–25 PDs before cessation of growth. Cells of the exposed lines, on the other hand, have undergone 40–42 PDs to date, and proliferation rates have decreased to a level of 1.5–1.7-fold increase over a 4-week period. Light exposures have been reduced to two per week, and the cultures are being maintained to determine if they can become established as continuous cell lines.

Although the proliferation rate of human fibroblasts in culture may be increased by a number of environmental factors including the volume of culture medium per cell[3], serum concentration[3], medium formulation (R. Parshad, unpublished). and intermittent light exposure[1], the only factor shown to increase proliferation rate as well as extend the lifespan reproducibly is the addition of cortisone or hydrocortisone to the medium[4]. The addition of hydrocortisone to the medium of W1–38 cells increased the PDs 30–40% above those of untreated controls. The duration of

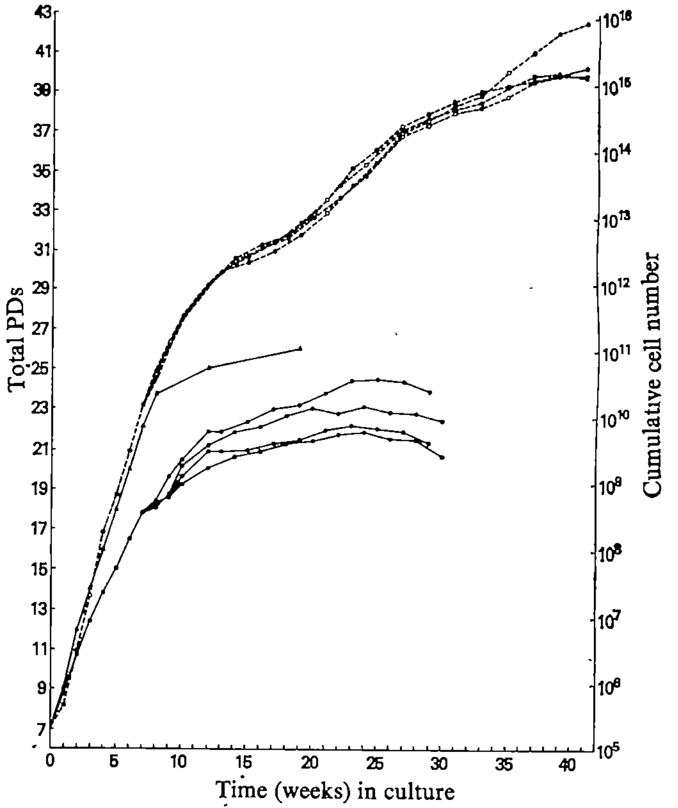

Fig. 1 Effect of intermittent light on lifespan of human skin fibroblasts, line HU-274, derived from a 50-yr-old black male who died of hypertension and renal failure. The cells grown in Dulbecco Vogt's medium supplemented with 10% foetal bovine serum had been carried for seven PDs as estimated from 1:2 or 1:4 split ratios before this experiment. In the quantitative studies, 2×10^5 cells were inoculated into 5 ml medium in a T-25 flask (Falcon). Light-exposed cultures were illuminated under two cool-white fluorescent light tubes (GE F 15T8/CW) at 27 cm from the floor of the flask with an exposure intensity of 6 to 9 W m^{-2} for 3 h, three times a week, 24 h after inoculation and twice thereafter following culture fluid renewal. After an interval of 1 or 2 weeks, depending on cell growth, the number of cells per flask was determined by haemocytometer. Cells from replicate cultures were inoculated at 2×10^5 cells per flask to continue the line and quantify as above. The PDs for the shielded, non-quantified cell line are based on 1:2 or 1:4 split ratios. Each point is the average of counts from four replicate cultures. Except for the light exposure described above, cells and culture medium were handled under red or gold light and were never exposed to light of wavelength below 500 nm. ●, Unexposed; ○, light exposed

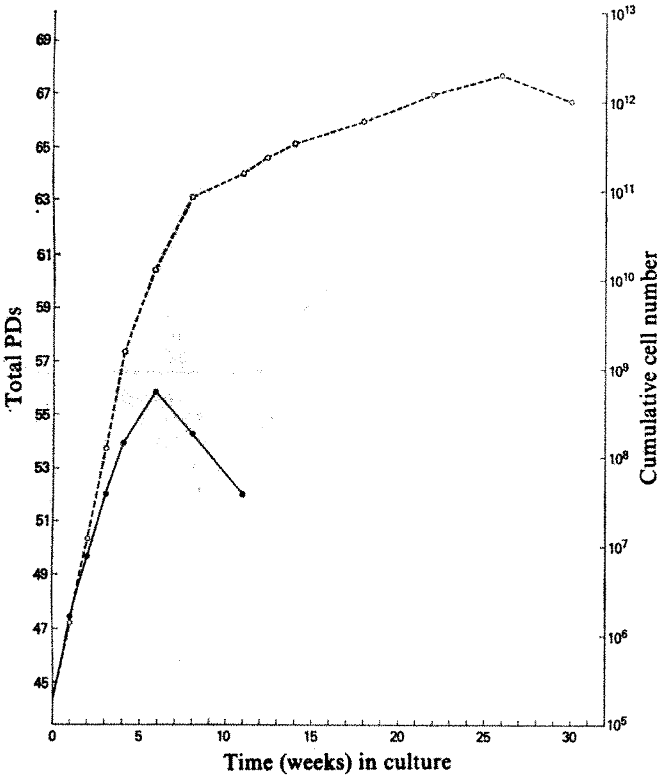

Fig. 2 Effect of intermittent light on lifespan of foetal lung WI-38 cells obtained at passage 17 from the American Type Culture Collection Rockville, Maryland. Before this quantitative experiment, cells had been carried in NCTC 135 with 10% foetal bovine serum for 21 PDs and in Dulbecco Vogt's medium for six PDs based on 1:4 or 1:8 split ratios. For experimetal details, see Fig. 1. ●, Unexposed; ○, light exposed.

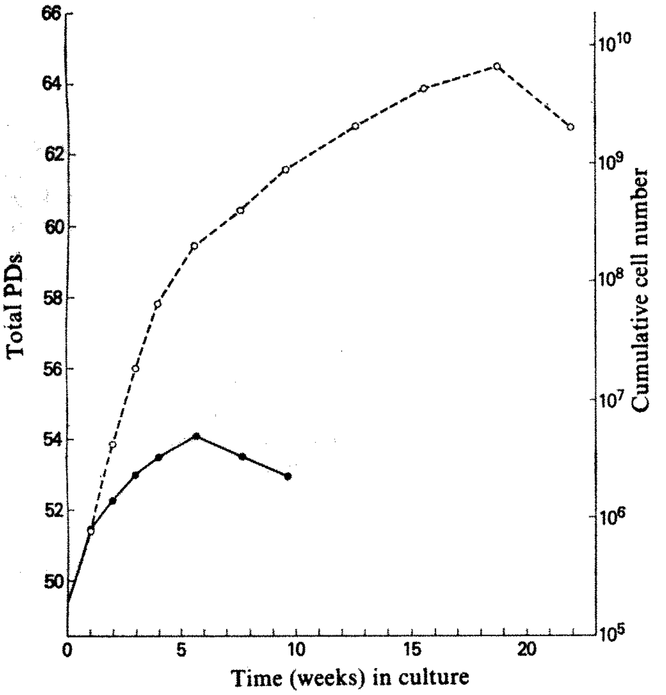

Fig. 3 Effect of intermittent light on lifespan of human foetal cells, line HU-278, derived from a mince of whole foetus. Before this quantitative experiment cells had been carried in NCTC 135 with 10% foetal bovine serum for 38 PDs before cryopreservation, and for 11.5 additional PDs in Dulbecco Vogt's medium based on 1:4 or 1:8 split ratios. For experimental details, see Fig. 1. ●, Unexposed; ○, light exposed.

Table 1 Effect of intermittent light exposure on lifespan (PDs of) human fibroblasts in culture

Cell line	Initial PD before light exposure	Additional PDs* Unexposed	Additional PDs* Exposed	% Increase in exposed to total unexposed PD†
HU-274-1	7	17.53	34.79	70.40
-2	7	15.07	32.73	80.02
-3	7	14.55	32.70	84.22
-4	7	12.56	32.76	98.02
HU-278	49.5	4.66	15.04	19.17
W1-38	44.5	11.44	23.25	21.11

*PD (x) was calculated by the equation $N = N_0 2^x$. Where N_0 = initial cell number and N = final cumulative cell number.

†PD of exposed − PD of unexposed ÷ Initial PD + PD of unexposed × 100.

life in culture for both control and treated cells, however, was the same. Intermittent light treatment, here, of W1–38 cells increased the PDs 100% above those of unexposed controls. When intermittent light exposure of adult skin cells (HU-274) was started early in culture, the maximum increase in PDs was 160% above those of unexposed controls. In all three cell lines, the duration of life in culture was also greatly increased.

Although cytotoxic effects of fluorescent light on cells in culture have been reported[5], Litwin[6] observed an increased lifespan but no enhanced proliferation rate in human embryonic fibroblasts when exposed to light for 2 or 4 h daily. In the conditions of the present study, which include a relatively high inoculum size, low light intensity, and short duration of exposure, stimulation of proliferation rate and extension of lifespan were observed in all three cell lines of adult or foetal origin. We have shown previously that the stimulation of proliferation by fluorescent light is mediated through the culture medium. The extension of lifespan may likewise be associated with photochemical changes in some component(s) of the medium.

Contact-mediated communication of ouabain resistance in mammalian cells in culture

THE active transport of Na^+ and K^+ across the plasma membrane, mediated by Na^+-K^+-ATPase, can be inhibited specifically by the cardiac glycoside ouabain[1]. Ouabain is toxic to mammalian cells in culture, the degree of sensitivity varying with species[2]; however, cells resistant to its cytotoxic effects have been obtained in rodent[2–4] and human[5,6] cell strains. Ouabain-resistant (oua^r) cells are thought to have a mutation affecting the Na^+-K^+-ATPase so that their enzyme has a lower affinity for ouabain than the enzyme of ouabain-sensitive (oua^s) cells. Therefore, oua^r cells can actively transport Na^+ and K^+ at ouabain concentrations that would inhibit oua^s cells[2,4,5]. We have observed that oua^s human cells, when cocultured densely with oua^r human cells, acquire a functional resistance to ouabain as evidenced by their ability to proliferate in medium containing the drug (unpublished observations). We suspected that ouabain resistance was communicated from oua^r to oua^s cells and that this transfer was a manifestation of ionic transport through a pathway independent of the Na^+-K^+-ATPase. There is substantial evidence that a specialised membrane structure, the gap junction, is the ultrastructural pathway for the transfer of ions, metabolites and other small molecules between cells in contact[7–9]. To determine whether the acquisition of ouabain resistance we observed was mediated through gap junctions, we have compared—for the ability to communicate ouabain resistance—cells which are known to form gap junctions with those that cannot. Our results indicate that ouabain resistance can be communicated from oua^r to oua^s cells, that the process is contact dependent and that it does not occur in cells unable to form gap junctions.

To assay for communication of ouabain resistance, we analysed chromosome preparations obtained from mixed cultures of oua^r and oua^s cells in ouabain for the presence of metaphase cells of oua^s origin. The ability of oua^s cells to divide in ouabain would provide definitive evidence that the sensitive cells had acquired resistance We used mouse fibroblasts as the oua^r cells and human fibroblasts as the oua^s cells for the following reasons. Mouse and human metaphases are distinguishable by conventional staining techniques (Fig 1). Mouse cells are naturally 10^4-fold more resistant to ouabain than human cells, so they can proliferate in 10^{-6} M ouabain, whereas human cells cannot. There are mouse cell strains that form gap junctions, and others that do not. The oua^r cells were therefore (1) mouse 3T3 fibroblasts, which are known to be communicating because they form gap junctions[10], ionically couple[11] and transfer nucleotides[12], and (2) mouse L fibroblasts known to be non-communicating because they do not form gap junctions[7,8] and do not transfer ions[7,8] or nucleotides[7,8,12–14]. The oua^s cells were a strain of human skin fibroblasts (no. 106) isolated in our laboratory from a 2-yr-old female, they were used in their 5–8th subculture and have been shown to communicate nucleotides[6,14] Human skin fibroblasts are known to form gap junctions and transfer ions[8].

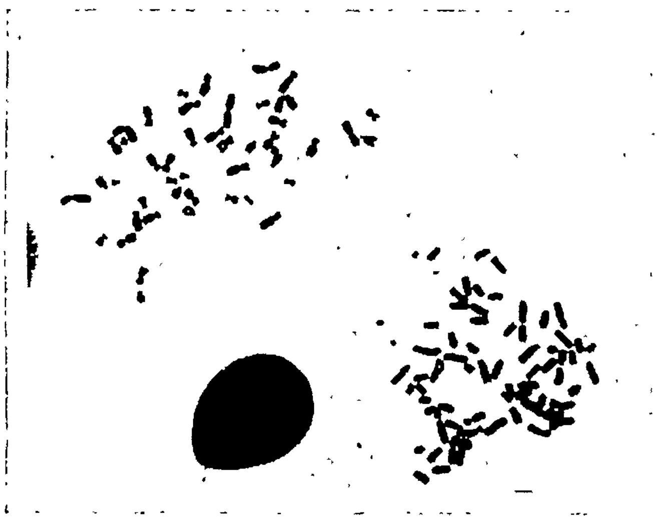

Fig. 1 Photomicrograph showing human and mouse metaphases from mixtures of human and 3T3 cells in 10^{-6} M ouabain Chromosome preparations were made *in situ*: the cells on 22-mm² coverslips were exposed to colchicine (0.4 μg ml^{-1}) for 1 h, 0 075 M KCl for 5 min, and 3.1 methanol·acetic acid for 30 min at 4 °C Coverslips were then immersed in ice-cold water, dried on a hot plate and stained with Giemsa. A clone of 3T3 cells with very few metacentric chromosomes was used to facilitate discrimination of the metaphases as either mouse or human. (× 663.)

Table 1 Percentage human metaphases of total metaphases in cultures of human and mouse cells plated into control and ouabain medium

Experiment	Cells	Ouabain conc in medium	Total metaphases	% Human metaphases
1	Human	0	200	100
		10^{-6} M	0	0
	Human+L	0	200	45
		10^{-6} M	200	0
	Human+3T3	0	200	54
		10^{-6} M	200	51
2	Human	0	200	100
		10^{-6} M	0	0
	Human+L	0	200	50
		10^{-6} M	200	0
	Human+3T3	0	200	55
		10^{-6} M	200	49

For experiment 1 cells were plated on to 22-mm² coverslips in 35-mm dishes containing 2 ml of medium and incubated at 37 °C in 5% CO_2. After 24 h of cultivation, the medium was renewed to ensure stringent selection. After 48 h, coverslips were fixed and stained for chromosome analysis as described in Fig 1 For experiment 2 cells previously plated on to 22-mm² coverslips were transferred to the same 100-mm dish (Fig 2) and then treated as in experiment 1. In both experiments cells were plated at the same densities—10^5 human cells and 5×10^4 mouse cells per 35-mm dish Cells were maintained in growth medium (Eagle's minimal essential medium supplemented with non-essential amino acids, glutamine, penicillin-streptomycin, fungizone and 20% foetal calf serum (Gibco)) Growth medium containing 10^{-6} M ouabain is referred to as ouabain in the text. Human metaphases were distinguished from mouse at ×100 magnification

The human cells were plated alone or co-cultivated with either L or 3T3 cells at densities ensuring cell contact[13,14] in medium containing 10^{-6} M ouabain (hereafter referred to as ouabain). For a control, a similar series was plated into non-selective medium The cultures were incubated, as described in Table 1, and then chromosome preparations were made. Analysis of the metaphase spreads (Table 1, experiment 1) revealed, as expected, that L and 3T3 cells divided in ouabain, whereas human cells, when plated alone, did not In the mouse–human cell mixtures plated into ouabain, no human metaphases were found when human cells were co-cultivated with L cells; however, abundant human metaphases were observed when human cells were co-cultivated with 3T3 cells (Fig. 1). Thus, human cells were able to acquire ouabain resistance from 3T3 cells but not from L cells.

To assure that the communication of ouabain resistance observed in the 3T3–human cell mixtures was not attributible to passage of molecules through the medium, the experiment was repeated in the following conditions. Coverslips containing the cell mixtures and appropriate controls were transferred to the same large Petri dish containing either ouabain or non-selective medium (Fig 2) The results of metaphase analysis from this experiment (Table 1, experiment 2) were identical to those of experiment 1 in which cells had been incubated in individual Petri dishes. The human cells on the same coverslip with 3T3 cells were able to divide in ouabain, whereas human cells in the same dish, but not on the same coverslip with 3T3 cells, were unable to divide. The absence of human metaphases on coverslips containing human cells alone or in combination with L cells not only confirms that L cells cannot transfer ouabain resistance, but also indicates that the communication of ouabain resistance seen with 3T3 cells does not occur through the medium. Moreover, increasing the ratio of 3T3 to human cells (by floating a 22-mm² coverslip containing human cells on a confluent lawn of 3T3 cells in a 100-mm dish) did not enable the human cells to divide in ouabain (data not shown). The best interpretation for our observation is that the communication of ouabain-resistance is dependent on contact between human and 3T3 cells.

Our results demonstrate that L cells, characterised by an inability to form gap junctions, cannot confer ouabain resistance on oua^s cells, whereas 3T3 cells, which are able to form gap junctions, can transfer ouabain resistance This provides compelling evidence that the gap junction mediates the communication of ouabain resistance and also suggests a molecular basis for this communication. There is substantial evidence from experiments

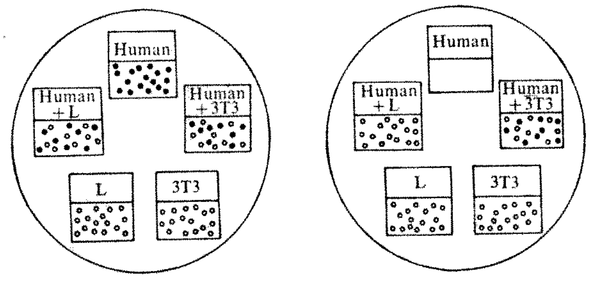

Fig. 2 Experiment demonstrating that communication of ouabain-resistance does not occur through the medium. Mouse and human cells, as indicated, were plated on to 22-mm^2 coverslips in individual 35-mm dishes containing non-selective medium. After cell attachment (5 h), the coverslips were transferred into a 100-mm dish containing 10 ml of non-selective (*a*) or ouabain (*b*) medium and treated as described in Table 1, experiment 2. The results of metaphase analysis are indicated schematically: ●, human metaphases; ○, mouse metaphases. In ouabain only the human cells on the same coverslip with 3T3 cells are able to divide.

involving both ultrastructural and electrophysiological techniques that Na^+ and K^+ can diffuse freely from cell to cell through the low-resistance pathways of gap junctions without leakage into the extracellular space[7–9,11,15–17]. Diffusion of Na^+ and K^+ through gap junctions between oua^r and oua^s cells would maintain the correct internal cationic balance in the oua^s cell, even though its own Na^+-K^+-ATPase is inhibited by ouabain.

Alternative explanations, for example, transfer of resistant Na^+-K^+-ATPases through gap junctions, are unlikely because these junctions are not permeable to molecules greater than 1,200 daltons[18]. The large proportion of responding cells precludes a rare event such as spontaneous mutation as a cause; in fact, we have not observed spontaneous mutations to ouabain resistance in 5×10^7 human skin fibroblasts[6]. Nor does the oua^r phenotype significantly affect the ability of a cell to communicate[6]. One cannot exclude the possibility that resistant Na^+-K^+-ATPases are transferred to the sensitive cells through focal membrane fusion, or diffusion in the immediate environ of resistant cells, but neither of these nor other mechanisms readily explain the observed differences between 3T3 and L cells. On the basis of our results, the most likely explanation is that resistance is transferred by diffusion of ions through gap junctions.

Synergism between anti-microtubule agents and growth stimulants in enhancement of cell cycle traverse

COLCHICINE and other mitotic inhibitors have been used widely in cell cycle studies to produce synchronous cell populations[1]. This application is based on the ability of these drugs to inhibit mitosis by binding to tubulin and preventing microtubule (mitotic spindle) formation[2]. As well as inhibiting mitosis, these drugs modify the morphology and functions of cells during interphase. For example, colchicine inhibits the formation of cilia[3], affects phagocytosis, the normal distribution of lysosomes[4], and the synthesis and secretion of various proteins[5–7] and alters the transport of certain nucleotides[8]. At very high concentrations ($2–35 \times 10^{-3}$ M) colchicine and colcemid retard the initiation of DNA synthesis and prolong the period of DNA synthesis[9]. We describe here the synergistic effects of colchicine and other anti-microtubule agents at lower concentrations ($1–2 \times 10^{-7}$ M) in the insulin- or serum-induced increase in cells moving from G_1 to S phase. Our results suggest that microtubules have an important role in the regulation of DNA synthesis by growth factors.

High density chick cells starved of serum can be stimulated synchronously by insulin to traverse at least one cell cycle[10]. This stimulation was detected as an increase in the proportion of cells in S phase with 8–10-h lag when the increase in DNA per cell was detected by flow microfluorometry (FMF). When similar experiments were performed in the presence of 2×10^{-7} M colchicine, it was evident that colchicine significantly increased the population in the S phase of the cell cycle (Fig. 1). The stimulated cells progressed through S phase more slowly than in the absence of colchicine, but the degree of synchrony was as good as the stimulated population when insulin was used alone.

Two other anti-microtubule agents, colcemid and vinblastines were compared with colchicine in their ability to affect the proportion of cells stimulated to make DNA in insulin-treated chick cell cultures. All of these compounds increased the cell population moving out of G_1 phase in the presence of insulin (Table 1). Colchicine and vinblastine were more effective than colcemid at lower concentrations. Furthermore, the continuous presence of anti-microtubule agents was not necessary, for their removal from the media after 6 h had the same effect (data not shown). These observations suggest that the primary effect of anti-microtubule agents at low concentrations is on the early events in the simulation of DNA synthesis. At higher concentrations ($> 5 \times 10^{-7}$ M), all of these compounds decreased the number of cells engaged in DNA synthesis, probably due to toxic side effects. Thus the mode of action of these drugs is different when compared at low and high concentrations.

To determine whether or not this stimulatory effect also applied to cell lines, the effect of anti-microtubule agents on BALB 3T3 cells was compared with that on chick fibroblasts. In these experiments cultures at their saturation density were stimulated with fresh medium containing either insulin or serum. The proportion of cells in the $S+G_2+M$ phases with or without added growth stimulants are listed in Table 2. As before, we found that insulin had little or no stimulatory effect on DNA synthesis in BALB 3T3 A31 cells. This was true even when the insulin concentration was raised to 128 mIU ml^{-1}. Similar results were obtained with Don hamster cells at high density (results not shown). Furthermore, only chick cells could be stimulated to synthesise DNA by fresh medium. It is important to note that colchicine was effective in stimulating cell movement from G_1 to S only

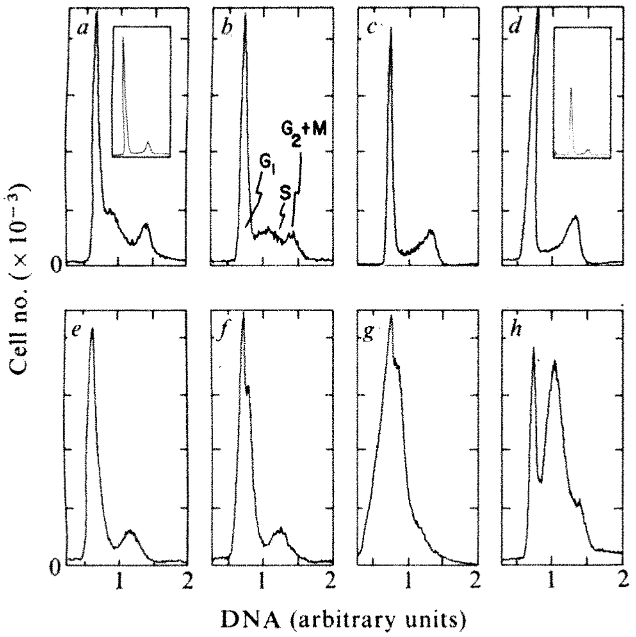

Fig. 1 Progress of chick embryo fibroblasts through the cell cycle in the presence of insulin and colchicine. Confluent secondary chick embryo fibroblasts in medium 199 were prepared and deprived of serum as described before[10]. After serum starvation, insulin was added at a concentration of 16 mIU per ml medium. Parallel cultures were provided with insulin and 2×10^{-7} M colchicine and were incubated in 5% CO_2 at 39 °C. Cells were collected and prepared for FMF analysis, using propidum iodide as the fluorescent stain[25]. FMF patterns of insulin-treated cultures are *a–d* for the time points of 13, 17, 23 and 29 h respectively, and insulin plus colchicine are *e–h* for the same time sequence. The inserted histograms in (*a*) and (*d*) are control cultures in medium 199 at 0 and 29 h. Histograms were plotted to give the peak channel at approximately the same height. The number of cells ($\times10^3$) in the peak channel was *a*, 2.7; *b*, 1.0; *c*, 1.3; *d*, 5.5; *e*, 4.0; *f*, 2.2; *g*, 4.0 and *h*, 3.5.

when the primary growth stimulant, a mitogen, was able to stimulate some cell cycle traverse. Therefore, colchicine and other anti-microtubule agents act as 'synergistic agents' to a 'mitogen'.

How does the message for DNA synthesis get transferred from the mitogen to the cell? The cell membrane is believed to have an important role in such progress. Some growth stimulants have been partially purified from various sources, and shown to bind to the surface membrane of cultured cells[11–13]. What occurs between the binding of growth stimulants and their relation to the initiation of DNA synthesis is, however, poorly understood.

The dynamics of the membrane receptors and other components seem to be subject to controls from both sides of the membrane. For example, concanavalin A (con A) and other related plant lectins inhibit the immunoglobulin capping on lymphocytes[14,15]. Con A by itself can form caps on various cell types and the process is either inhibited or stimulated by anti-microtubule or anti-microfilament agents depending on cell types studied[15–18]. But, the evidence for the involvement of microtubules in growth regulation has been of a 'negative' nature so far, that is, agents affecting these organelles would inhibit the stimulatory action caused by a mitogen[9]. Most of these studies were carried out at high concentrations of inhibitors, where possible toxic side effects could have complicated the interpretation of the results. Our evidence of the positive effect of anti-microtubule agents on mitogen-stimulated DNA synthesis directly demonstrates involvement of microtubules in growth regulation.

Table 1 Effect of colchicine, colcemid and vinblastine on cell cycle traverse of insulin-treated chick embyro fibroblasts

Concentrations of mitotic inhibitors (M)	% of cells in $S+G_2+M$ phases Colchicine	Colcemid	Vinblastine
0 (insulin only)	25	25	25
5×10^{-8}	47	27	58
1×10^{-7}	60	25	64
2×10^{-7}	69	54	60
5×10^{-7}	64	62	63

Cells were grown and prepared for FMF analysis as for Fig. 1. Colcemid, vinblastine, and colchicine were tested at the concentrations indicated. Insulin was present in all cultures. Cells were collected 22 h after addition of mitotic inhibitors and insulin. After FMF analysis, the % population in $S+G_2+M$ phases were calculated with a computer program.

The presence of insulin receptors on chick fibroblasts has been demonstrated in detail[19]. Furthermore, site–site interaction and redistribution of insulin receptors after the binding of insulin to the membrane of rat liver or human lymphocytes have been reported[20]. The striking synergistic effect of colchicine and insulin on stimulation of DNA synthesis in chick fibroblasts reported here makes it possible to propose the following model to explain such synergism (Fig. 2). In this model which is a modification of that proposed by Nicolson[21] and by McGuire and Barber[22], a growth stimulant after binding activates its receptor on the membrane by forming an active stimulant–receptor complex. To complete a signal for DNA synthesis, however, cooperation of this complex with certain membrane components must take place. If the mobility of membrane receptors and second components is an important factor in the signal transfer, any compound which increases this mobility should facilitate DNA synthesis. Microtubules have been proposed to be an anchorage agent for certain membrane components[14,21]. Our results indicate that this may indeed be the case. A factor which destroys microtubule structure, colchicine in this case, can be a synergistic agent for growth stimulation. Such an agent by itself is incapable of triggering DNA synthesis. It acts only when some DNA synthesis capacity is already present.

Table 2 The effect of colchicine and growth stimulants on cell cycle traverse

Cell types and media	% of cells in $S+G_2+M$ phases −Colchicine	+Colchicine
Secondary chick embryo fibroblasts		
Medium 199 (control)	14	32*
+insulin, 16 mIU ml⁻¹	29	66
+chick serum, 3%	33	58
BALB 3T3 A31		
Medium DME (control)	4	4
+insulin, 128 mIU ml⁻¹	4	4
+calf serum, 10%	15	29
+calf serum, 20%	30	78
+calf serum, 30%	33	90

Data for secondary chick embryo fibroblasts were obtained as described in Table 1. Values are averages of two experiments. BALB 3T3 A31 cells were grown to confluency in medium DME containing 10% calf serum for 5 d. Cells were washed with saline and provided with fresh medium DME containing additional components indicated. After 28 h, cells were collected and prepared for FMF analysis.

*The degree of stimulation on cells in medium 199 (control) varied with each experiment depending on the batch of cells.

It has been reported that BALB 3T3 cells indeed have insulin receptors[23]. But binding of insulin to these receptors fails to stimulate DNA synthesis in these cells (ref. 10, and the results here). In addition, the cell line of this type and human diploid foreskin or ovine embryonic trachea fibroblasts fail to show growth stimulation on addition of trypsin, an agent which stimulates growth in secondary

Some probability of cell growth
Increased probability of cell growth

Fig. 2 Schematic representation of message transfer. The inactive receptor for 'growth stimulant (mitogen)' and 'second component' for carrying on message transfer are distributed randomly on the membrane, and their mobilities are controlled by membrane fluidity which in turn, is influenced by the cytoplasmic microtubules along the inner side of the membrane. When anti-microtubule agents are present, the cytoplasmic microtubules are depolymerised and the mobilities of membrane components increase. Thus, the chance of interaction between the activated receptor complex and the second component is higher and the message for DNA synthesis is transferred much more efficiently.

chick fibroblasts[24]. The most likely explanation is that there is fundamental difference in the nature of membranes of primary cell cultures and cell lines. It is possible that the interaction between mitogen receptor complex and second membrane component is blocked in cell lines unless a more complicated factor such as serum is provided to potentiate the cooperation. Alternatively, the activation of certain mitogen receptors, for example, insulin receptors, may not occur after the binding of the mitogen. Therefore, no message is generated and transferred to the second component. There is an additional possibility that the second membrane component for message transfer from particular single growth factor may be altered in cell lines. As a result, the growth control of cell lines in culture becomes much more stringent than that of primary cell cultures as discussed previously[10]. The exact nature of the synergistic effects of anti-microtubule agents and growth stimulants is currently under investigation.

5-Hydroxytryptamine and punishment

PUNISHMENT is defined as the presentation of a noxious stimulus and results in the suppression of behaviour. This suppressive effect of punishment is seen clearly in conflict situations where the organism is encouraged to respond and then is punished for doing so. Brain 5-hydroxytryptamine (5-HT) systems have been implicated in the processes associated with the response to punishment. We show here that selective neurotoxin lesions to the 5-HT forebrain pathways reverse the suppressive effects of punishment, as do minor tranquillisers, supporting the view that 5-HT has a central role in conflict behaviour and in the effect of minor tranquillisers on such behaviour.

If a response is followed by punishment, the probability of its occurrence decreases. 5-HT antagonists[1-3] and synthesis inhibition[4-6] have been shown to re-instate rates of punished responding. Furthermore, behavioural release following synthesis inhibition has been shown to correlate closely with the pharmacological time course of 5-HT depletion[6]. Qualitatively similar behavioural effects have been reported with anxiolytic drugs such as the benzodiazepines and with pharmacological studies in support, it has been suggested that at least part of the anti-anxiety action of these drugs is due to decreased 5-HT functional activity[7]. But, the lack of neuropharmacological specificity associated with the existing methods for reducing 5-HT activity makes clear experimental investigation of this hypothesis difficult.

The neurotoxic agent, 5,7-dihydroxytryptamine can be injected directly into the brain to destroy 5-HT neurones. Stein and colleagues[8] have reported a profound, although transitory, release of punished behaviour in a conflict paradigm, accompanied by little effect or unpunished responding, following intraventricular injection of 5,6-dihydroxytryptamine (5,6-DHT). Neurotoxic indoleamines have been injected into specific brain areas[9] and the balance of neurochemical data (for instance ref. 10) suggests that 5,7-DHT produces minimal nonspecific degeneration. Therefore, intracerebral injections of 5,7-DHT were used to provide more direct evidence for a role of 5-HT in punishment processes.

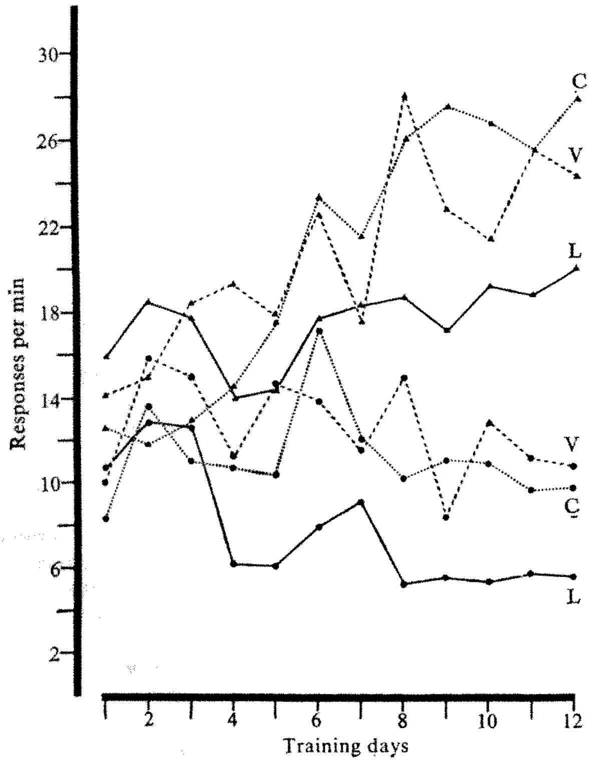
Male Sprague–Dawley rats (250–300 g) were trained to press a lever for food reward on a continuous reinforcement (CRF) schedule. Following this they were randomly divided into three groups. 5,7-DHT creatinine sulphate (Regis) ($n = 8$, 2 μg per 2 μl free base, on each side of brain) or vehicle ($n = 5$, 1 mg ml^{-1} ascorbic acid in sterile isotonic saline) was injected (1 μl min^{-1}) bilaterally into the ventromedial tegmentum. Operated control animals ($n = 5$) underwent the same procedure except that the injection needle was not lowered into the brain. This latter group was included to assess any behavioural disturbances due to 5-HT depletion in vehicle injected animals observed in an earlier pharmacological study. Ether anaesthesia was used and all animals received desmethylimipramine (25 mg per kg body weight, intraperitoneally, since this prevents the effects of 5,7-DHT on NA neurones)[11,12] 45 min before surgery. The incisor bar was set 3.2 mm above the intra-aural plane and coordinates taken from the lambda (+1 mm) skull suture (caudal, 6.5 mm; ventral, 11.3 mm; lateral, 0.5 mm; injection needle introduced at an angle of 47° to the vertical plane).

After surgery, free-feeding weight was reduced to 85% and the effects of the surgical treatments were examined on the acquisition of a multiple three component schedule involving two reward components and a time-out period. The three components were signalled by different light conditions—during the first reward component (10 min) the illumination was provided by the house light alone, time-out (4 min) was signalled by darkness; and during the second reward component (4 min) both the house light and lever lights were on. This sequence, reward (1), time-out, reward (2) was presented twice during each testing session. Reinforcement in the reward components was available on a variable interval (VI) 25 s (with limits of 5 and 55 s) schedule. No reinforcement was programmed during time-out. Animals were tested on this schedule for 12 consecutive days, (training days 1–12).

During the following 6 d (days 13–18) the second reward component was changed to a conflict situation—reinforcement was again available on the same VI schedule. Each reinforced response, however, was also punished (0.8 mA electric shock of 0.5 s to the feet).

Mean responses per minute over successive training days 1–12 for each surgical group in the reward (1) and time out components are shown in Fig. 1. Although lesioned animals tended to respond at a lower rate no overall significant differences were observed between groups during 12 d of acquisition training on the two reward components of the multiple schedule (Kruskal–Wallis, reward (1) $H = 2.62$, $P > 0.20$; reward (2), $H = 4.45$, $P > 0.10$). Furthermore rates of responding in these two components did not differ within each surgical group. But a similar analysis showed a significant overall difference between groups during acquisition of the time-out component ($H = 13.79$, $P < 0.01$). Inspection of the data showed that this was due to less responding by the lesioned animals.

Fig. 1 Response per minute for each surgical group (C, control; V, vehicle; L, lesion) during the training days 1–12 (postoperative days 11–23). ▲, Responding during reward (1); ●, responding during time-out component. The three experimental groups are denoted with different line markings.



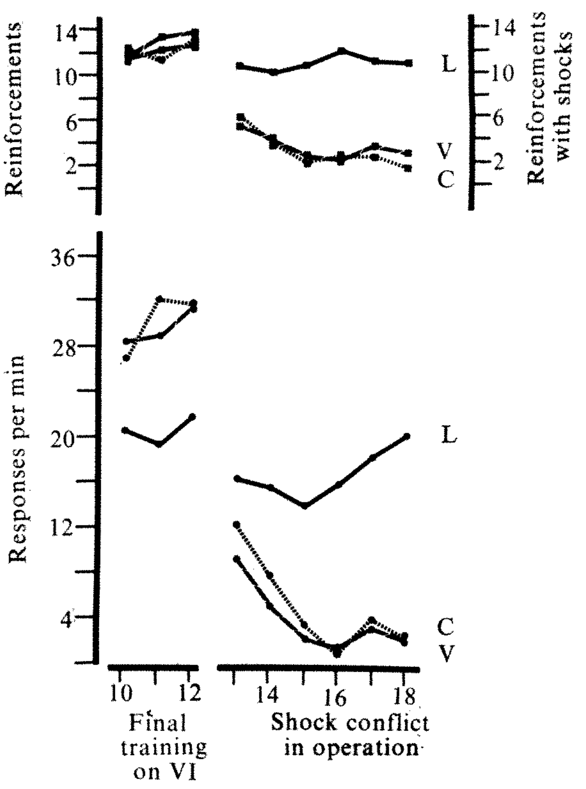


Fig. 2 Third schedule component. Left axis, responses per min and mean reinforcements received for each surgical group (during reward component 2) on the final three training days. Right axis, responses per min (●) and mean reinforcements plus shocks (■) during reward component 2 (now conflict component) for each surgical group (C, control; V, vehicle; L, lesion) on the 6 days of conflict following acquisition training. The experimental groups are denoted with different line markings.

The effects of shock introduction on response rate and shock acceptance in the former reward (2) component are shown in Fig. 2. This manipulation resulted in a dramatic decrease in response rate in both the control and vehicle groups. No suppression was observed in the lesioned animals, however, and correspondingly these animals accepted more shocks. These differences were highly significant overall (responses, $H = 11.56$, $P < 0.01$; shocks, $H = 12.38$, $P < 0.01$) and were observed until the end of behavioural testing on post-operative day 77. No significant overall differences were observed during reward (1) ($H = 3.66$, $P > 0.10$) although lesioned animals continued to respond at a lower rate during time-out ($H = 6.68$, $P < 0.05$).

For biochemical analysis animals were killed on post-operative days 97 and 98 and amine uptake into cortex slices and hypothalamic synaptosomal preparations determined[13,14]. With respect to controls, lesioned animals showed highly significant reductions in 5-HT uptake both in the cortex (77%) (Mann–Whitney test $P < 0.002$) and hypothalamus (66%) ($P < 0.004$) while the vehicle group showed much smaller non-significant reductions (cortex, 25%; hypothalamus, 7.5%). Uptake of noradrenaline in the cerebral cortex was not significantly altered (Mann–Whitney, $P > 0.8$) in any group of animals (vehicle 11%, 5,7-DHT 15% increases of sham). Uptake of hypothalamic noradrenaline was not measured in these experiments but identical 5,7-DHT lesions in a separate series had no significant effect on this parameter, while producing the same pattern and degree of 5-HT denervation[15]. Everitt (in preparation) has also shown no changes in dopamine uptake in septum or striatum after 5,7-DHT lesions in the MFB. Histological analysis of the lesion procedure has shown the canula placement to be localised in the decussation of the brachium conjunctivum dorsal to the interpeduncular nucleus.

Taken together these findings provide strong support for the postulation of a 5-HT 'punishment' system that is critically involved in the acquisition of behavioural suppression in conflict situations. In other experiments, previously acquired suppression was also found to be released by the 5,7-DHT lesion. The punishment-releasing effect of 5-HT depletions does not seem to reflect a nonspecific concommitant of a general release syndrome since the lesioned animals did not show higher rates of responding during the other schedule components. Reduced effectiveness of the electric shock in suppressing responding could be attributed to a reduced pain sensitivity. This is an unlikely interpretation of the results, however, as morphine, a classic analgesic does not re-instate shock-suppressed responding[16] and Hole[17] has reported that 5,7-DHT injections at sites in the midbrain similar to those used here have no effect on pain sensitivity.

It would be interesting to establish if chlordiazepoxide induces characteristic behavioural effects in 5,7-DHT lesioned rats. The most important of these effects is the ability of the minor tranquilisers to reinstate responding suppressed by punishment. But, this is clearly difficult to investigate when, as we have shown, the 5,7-DHT lesion itself releases punished responding. Rates of responding during conflict should be equivalent in all groups of animals before the effects of an anxiolytic drug are evaluated. Preliminary investigations of this question were conducted on the present animals, when the initial conflict experiment and a study of the effects of amphetamine on this behaviour had been completed. On postoperative days 31–34 the animals were restabilised on the basic three-component conflict schedule. During the next 12 d the shock level during the conflict component was increased from 0.8 mA to 2.5 mA in four steps (1.3, 1.6, 2.0, 2.5 mA). The effects of chlordiazepoxide (1.26, 2.0 mg per kg) were studied. The increased shock level decreased significantly conflict responding in the lesioned animals. Chlordiazepoxide did not re-instate responding in these animals to the same degree seen in the control animals. These results may reflect a block of CDP action in the 5,7-DHT-lesioned rats. Caution must be exercised, however, because the lesioned animals were responding in conflict at a higher rate than controls despite the raised shock level. It is therefore possible that under CDP the lesioned rats reach their highest possible rate of responding sooner and thus a response-releasing effect of the normal magnitude was not possible. But it is tempting to speculate that 5-HT pathways have a central role in mediating both the effects of shock on responding and the reversal of these effects with benzodiazepines.

Intranigral kainic acid is evidence that nigral non-dopaminergic neurones control posture

THE substantia nigra has a key role in the control of posture and in the coordination of movements. This function is currently attributed to the dopaminergic neurones ascending from the pars compacta of the nigra to the neostriatum. In fact unilateral lesion of this pathway by intranigral injection of 6-hydroxydopamine (6OH-DA) produces a dramatic asymmetry consisting of a tendency of the animal to turn towards the side of the lesion (ipsilateral turning)[1]. But, unilateral electrolytic lesions of the substantia nigra, while similarly effective to 6OH-DA in destroying dopaminergic neurones, result in turning towards the intact side (contralateral turning)[2,4]. This has been taken to indicate the existence of non-dopaminergic neurones arising from or traversing the nigra, which control turning behaviour in a manner opposite to the nigro-neostriatal dopaminergic neurones[2,4]. We report here that unilateral intranigral injection of kainic acid[5,6] produces a sustained contralateral turning independent from dopaminergic nigro-striatal function. Since kainic acid spares axons but produces neuronal loss in the pars reticulata of the nigra, our results indicate the existence of non-dopaminergic neurones originating in the pars reticulata which control turning behaviour and posture in a manner opposite to the nigrostriatal dopamine (DA) neurones.

Male Sprague–Dawley rats (290–310 g) were anaesthetised with Equithesin (3.5 mg per kg) and placed in a Stellar Stoelting stereotaxic apparatus; kainic acid (in saline) or 6OH-DA (8 μg of base in saline with 0.1% ascorbic acid) were injected in the substantia nigra using stereotaxic coordinates A-3, L 2, V 7.8, according to the Pellegrino and Cushman[7]. The total injection volume was 0.3 μl, injected at a constant rate of 1 μl per 18 min, through a 0.25-mm stainless-steel cannula. Unless specified, kainic acid was injected in the nigra at the dose of 0.75 μg. Twenty-four hours after intranigral kainic acid the intensity of turning behaviour was assessed as described in the legend to Table 1. Ten days after intranigral kainic acid 42 rats were killed, the brain perfused with formalin, included in paraffin and the mesencephalon cut into serial 20-μm slices which were stained with Luxol fast-cresylviolet in order to ascertain the location of the cannula tip and the extension of the lesion. In another series of rats, injected with kainic acid 10 d previously, the nigra of each side was punched out with stainless-steel cannulas from two 400-μm slices made by cryostat; glutamic acid decarboxylase (GAD), tyrosine hydroxylase (TH) and choline-acetyltransferase (CAT) were assayed according to McGeer and McGeer[6] with slight modifications.

Figure 1 shows the histological appearance of the substantia nigra injected with kainic acid 10 d previously as compared with that injected with saline, in sections stained with cresylviolet–Luxol fast blue. In the lesioned nigra the pars reticulata reveals moderate loss of neuronal perikarya and gliosis, characterised by proliferation of non-neuronal elements. The pars compacta seems less affected than the pars reticulata and still shows the presence of numerous large globose neurones. There are no signs of demyelinisation in or around the substantia nigra.

Intranigral injection of kainic acid produces homolateral turning which appears as soon as the animals recover from the anaesthesia and dominates the acute stage of the symptomatology, lasting about 6–12 h. As the ipsilateral turning subsides rats undergo a variable phase of intermittent ipsi- and contralateral turning but by 24 h after kainic acid administration they show an asymmetric posture with turning contralateral to the lesion.

As shown in Table 1, the intensity and the incidence of the contralateral turning is related to the dose of kainic acid, being maximal after 1.0 μg.

The contralateral turning is maximal during the first 3–4 d

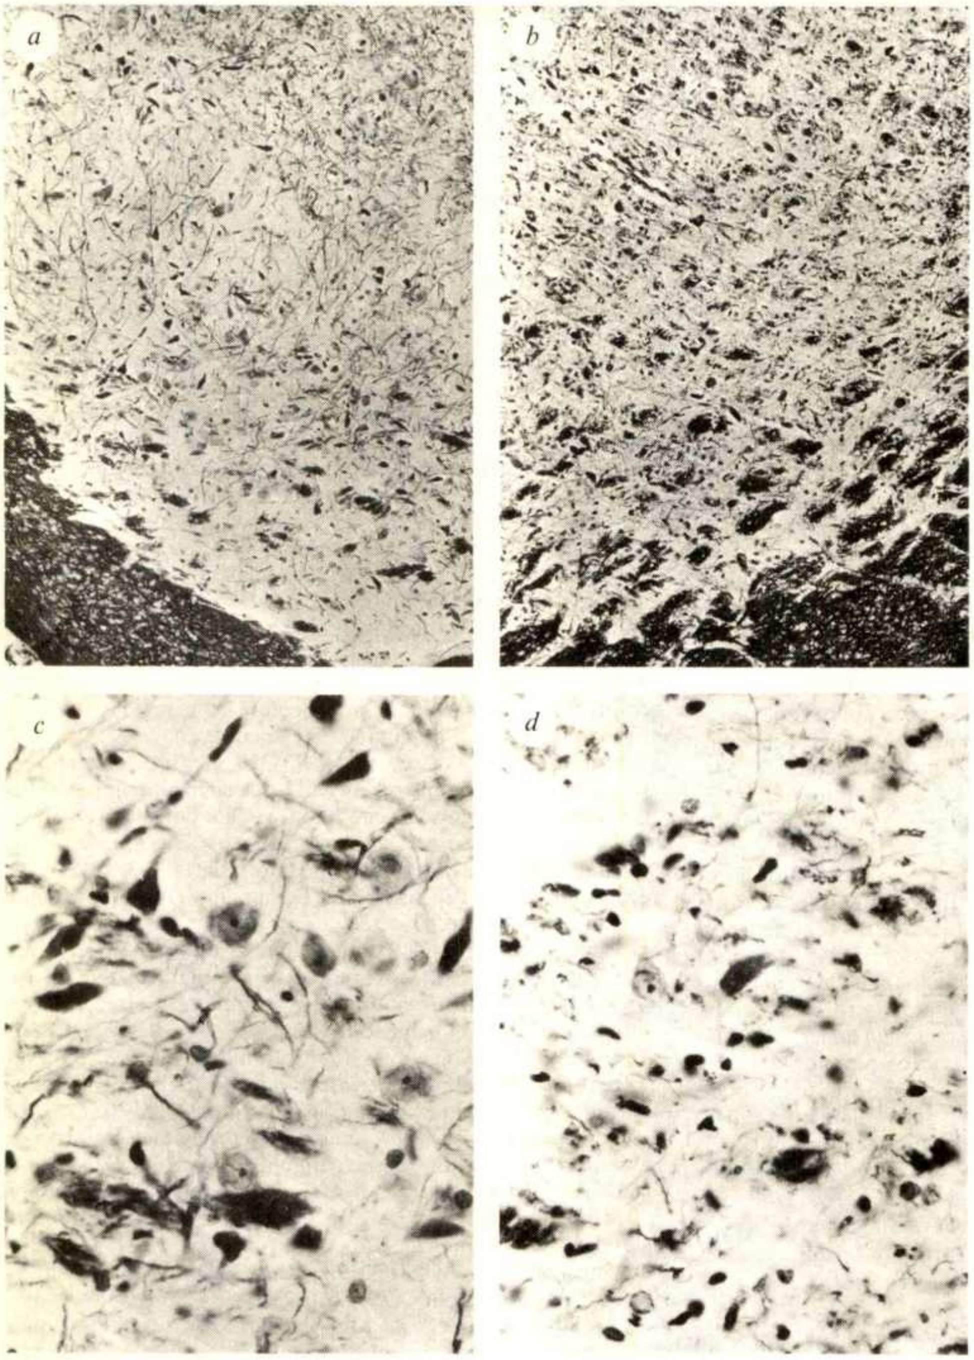

Fig. 1 Micrographs of Luxol fast–cresylviolet stained sections of substantia nigra pars reticulata from a rat injected unilaterally in the nigra with 0.75 µg of kainic acid, 10 d previously. *a*, *c*, Control side; *b*, *d*, kainic-injected side. *a*, And *b*, ×5; *c* and *d*, ×20.

after kainic administration and, although diminished in intensity, is still present 10 d later. Failure to obtain the chronic contralateral turning was associated, in 10 out of 12 rats, with placement of the cannual tip outside the substantia nigra. Among 30 rats where contralateral turning was obtained, the tip of the cannula was found to be placed in the centre of the pars reticulata in 16, at the border between the compacta and the reticulata in 8, in the pars lateralis in 4 and in the medial part of the nigra in 2 cases. Ten days after intranigral kainic acid nigral GAD and CAT in the kainic-injected side are not significantly different from the contralateral one while nigral TH is decreased by about 30% in the kainic-injected side (GAD: 965±45 compared with 987±52; CAT: 8.8±0.8 compared with 8.3±0.6; TH: 11.8±0.6 compared with 8.2±0.5; means ± s.e.m. of 10 determinations in control compared with kainic-injected side expressed in nmol per h per mg protein).

Bilateral intranigral administration of 6OH-DA, which decreased nigral TH-activity by more than 85% in respect to controls (see legend to Table 1), failed to affect the induction of chronic contralateral turning by kainic acid injected unilaterally in the substantia nigra (see Table 1).

Our results show that unilateral intranigral administration of kainic acid produces chronic contralateral turning. This effect was independent from an action on nigro–neostriatal DA-neurones, as it took place also when they had been previously destroyed bilaterally by intranigral 6OH-DA. Kainic acid produced a distinct loss of nigral neurones but did not damage myelinated fibres or change the activity of nigral GAD, a marker of afferent GABA-connections[8-10]. This indicates that the contralateral turning produced by intranigral kainic acid is due to destruction of nigral neurones rather than to damage of fibre tracts afferent to the nigra or passing near it.

Since the chronic effects of the kainic-induced nigral lesion are just opposite to the selective destruction of the nigrostriatal DA-neurones with 6OH-DA and are in turn unrelated to their intactness, our results indicate the presence, in the substantia nigra, of neurones controlling turning behaviour and posture in a manner opposite to the dopaminergic ones. Stimulation of

Table 1 Incidence and intensity of controlateral turning after various doses of intranigral kainic acid

Kainic acid (μg)	6OH-DA (8 μg)	Rats injected	Rats turning with score				Turns per 5 min*
			0	1	2	3	
0.25	—	10	8	2			—
0.50	—	15	5	2	7	1	15
0.75	—	30	6	2	6	16	32±5
0.75	+	20	3	1	4	12	35±7
1.0	—	20	1	1	4	14	38±6

Turning was scored 24 h after unilateral intranigral kainic acid according to Costall *et al.*[4]. 6OH-DA was administered in the nigra of both sides 15 d before kainic acid. In these rats, nigral TH was decreased by about 87% in respect to controls (1.5±0.4 compared to 12.2±2.5, mean ± s.e.m. of five determinations).

*Values are mean ± s.e.m.

these non-DA neurones by kainic acid would explain the homolateral turning obtained in the acute stage after intranigral kainic acid.

The chronic effects of the intranigral administration of kainic acid are strikingly similar to those obtained by electrocoagulative lesions of the nigra[2–4]. This suggests that the effects of the electrolytic lesions are due to destruction of nigral neurones rather to damage of fibre tracts.

As to the nature of the neurones destroyed by kainic acid, the fact that the loss of nigral perikarya is confined to the pars reticulata and that CAT activity is within the normal range, suggests that the lesion produced by kainic acid is limited to a fairly specific neuronal population. Indeed this would not be unexpected since the toxic effect of kainic acid, being related to stimulation of specific glutamate receptors[11], should vary among different neuronal types depending on the density of glutamate receptors on their perikarya. Accordingly, the relative intactness of the pars compacta and the minor reduction of nigral TH after intranigral kainic acid as compared with the dramatic decrease of striatal GAD and CAT after intrastriatal kainic acid[5,6], suggests that the dopaminergic nigral perikarya are much less sensitive to the toxin than striatal GABA-ergic and cholinergic perikarya.

The histological procedure adopted in this study does not permit the morphological identification of the nigral neurones destroyed by kainic acid. But, in view of the existence of nigral non-DA neurones projecting to the thalamus, to the reticular formation or to the striatum[12–16], lesion of these pathways could be the cause of the chronic effects of intranigral kainic acid.

The existence of nigral non-DA neurones controlling turning behaviour in a manner opposite to the nigrostriatal DA-system can provide an explanation for some turning responses obtained from the nigra which are not readily explained by an action on the nigrostriatal DA-system. For example, unilateral intranigral administration of ethanolamine-*O*-sulphate, which produces an accumulation of endogenous GABA by blocking GABA-transaminase, results in spontaneous contralateral turning[17,18]. This syndrome resembles the chronic one produced by intranigral kainic acid and therefore might be due to a GABA-mediated depression of those nigral neurones destroyed by kainic acid.

Enkephalin receptors on dopaminergic neurones in rat striatum

THE idea that morphine and other narcotic analgesics as well as opioid peptides affect the activity of nigrostriatal dopaminergic neurones is well supported. For instance these substances elicit changes in motor activity similar to those observed after blockade of dopamine (DA) receptors by neuroleptics, they increase DA turnover in striatum and several typical symptoms of the abstinence syndrome they provoke involve dopaminergic systems (see refs 1–3 for reviews). In agreement with these observations, a high density of 'opiate receptors'[4] and of enkephalin binding sites[5,6], a high content in enkephalins[7] and a dense network of enkephalin-containing neurones[8] are found in the striatum. All these observations suggested the possible connection between alleged enkephalinergic neurones and the dopaminergic fibres ending in the striatum. We report here that both the regional distribution of high affinity (morphine-displaceable) binding sites for leucine-enkephalin (Leu-enkephalin) in striatum and their decreased number after chemical or mechanical interruption of the nigrostriatal bundle support the assumption that enkephalinergic neurones terminate presynaptically on dopaminergic nerve terminals in the striatum.

^{3}H-Leu-enkephalin binds to a particulate fraction from rat striatum and the saturation kinetics at equilibrium evidence two distinct sites; the first one, exhibiting a high affinity (K_d around 3 nM) and recognised by morphine or naloxone, has been identified as the 'opiate receptor' whereas the nature and possible function of the second one is not yet established[5,6]. We have determined the number of binding sites for ^{3}H-Leu-enkephalin displaceable by morphine in successive frontal sections of rat striatum (Fig. 1). The density of these sites decreases regularly from the head to the tail of the striatum, with a twofold variation between the first and the last dissected area. The topographical variation of DA content (Fig. 1), in agreement with the report of Tassin *et al.*[11], grossly parallels that of the sites of ^{3}H-Leu-enkephalin binding displaceable by morphine. Since

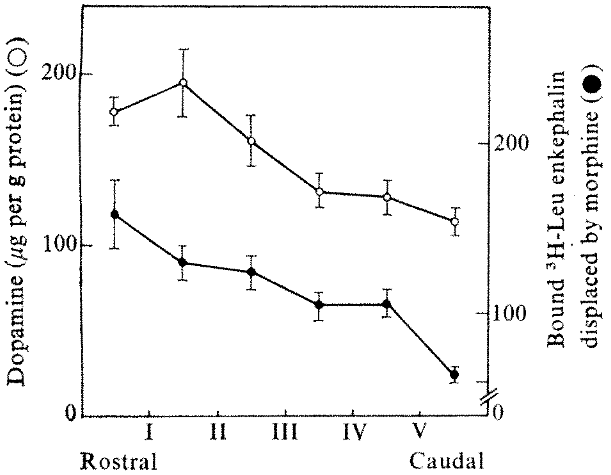

Fig. 1 Distribution of ^{3}H-Leu-enkephalin binding sites displaceable by morphine and DA content in frontal sections of rat striatum. The rat striatum was dissected according to Glowinski and Iversen[9], applied on a cold plate and divided into six serial slices. The first section was performed at the level of the anterior commissure (arrow) and therefore slice I included a portion of n. accumbens in addition to striatal tissue; the remaining tissue was then divided into five parallel slices of equal thickness. The good reproducibility of the dissection procedure was indicated by a variation of less than 6% between the protein content of homologous slices in different experiments. Homologous slices from four animals were pooled together and homogenised in 20 volumes of cold 50 mM Tris buffer, pH 7.4. An aliquot of the homogenate was quickly removed and deproteinised with $HClO_4$ for DA assay[10]. Binding of ^{3}H-Leu-enkephalin[5,6] was measured on a particulate fraction of the homogenate obtained by two successive centrifugations (180*g* for 5 min, then 10,000*g* for 20 min). 15-min incubations at 30 °C in the presence of 20 μM bacitracin, and 12 nM ^{3}H-Leu-enkephalin (45.6 Ci mmol^{-1}, Radiochemical Centre, Amersham) alone or in the presence of 5 μM morphine. Bound ^{3}H-Leu-enkephalin is expressed as fmol per mg of protein and represents the binding displaceable by morphine. Means ± s.e.m. from five separate experiments with triplicate assays for ^{3}H-Leu-enkephalin binding and duplicate DA estimations. ○ Dopamine content. ●, ^{3}H-Leu-enkephalin binding sites.

the variation in DA content reflects the heterogeneous distribution of DA terminals, our results suggest that enkephalin receptors might be topographically associated with dopaminergic synapses.

The presence of enkephalin receptors on DA neurones themselves was investigated by evaluating the effects of selective lesions of the nigrostriatal neurones on ^{3}H-Leu-enkephalin binding. Degeneration of DA terminals was elicited either chemically by 6-hydroxydopamine (6-OHDA) or by electrocoagulation of the pars compacta of substantia nigra and neurochemically assessed by the reduction in 'dopa' decarboxylase activity (Table 1). Such lesions resulted after 6–22 d in significant decreases in ^{3}H-Leu-enkephalin binding displaceable by morphine. The similar decrease in ^{3}H-naloxone binding following the chemical lesions confirms that the high affinity binding sites of ^{3}H-Leu-enkephalin represent the 'opiate receptors'. To confirm that the observed changes were indeed related to the degeneration of DA neurones, we have more selectively destroyed the nigrostriatal DA system by careful unilateral microinjections of 6-OHDA into the substantia nigra in the conditions of Agid *et al.*[12]. Two weeks later the decrease in ^{3}H-Leu-enkephalin binding displaceable by morphine observed in the striatum of the lesioned side was by 27 ± 3% (means ± s.e.m. from nine animals) whereas the high affinity uptakes of ^{3}H-choline and ^{3}H-5-hydroxytryptamine[13] in striatal synaptosomes from the same animals were not significantly modified. In addition, we have observed significant decreases in ^{3}H-Leu-enkephalin and ^{3}H-naloxone binding (by 30–40%) in rats with the nigrostriatal bundle sectioned at the hypothalamic level 10–30 d before (in preparation).

The decrease in ^{3}H-Leu-enkephalin binding following electrocoagulation of the substantia nigra probably reflects a diminished number of receptor sites since the decrease affects the maximal binding on the high affinity sites without significant change in K_d (4.7 ± 0.8 nM on the control side compared with 4.2 ± 0.4 nM on the lesioned side) (Fig. 2).

Conceivably transynaptic degeneration may have a role in the observed changes but our observation, consistent with previous reports[14,15], that ^{3}H-choline uptake is not affected indicates that striatal cholinergic neurones, on which DA neurones project, do not degenerate transynaptically. It might also be argued that the decreased number of Leu-enkephalin binding sites is due to the interruption of a neuronal system other than the dopaminergic one (or the serotoninergic one which is unaffected after intranigral 6-OHDA). Such an hypothesis cannot be entirely ruled out but seems very unlikely because the decreased binding is elicited by three different types of lesions—electrolytic, mechanical and chemical—of which the common feature is to induce a degeneration of the DA terminals in the striatum.

Hence both the regional distribution of the high affinity Leu-enkephalin binding sites within the striatum and the decreased number of these sites after lesions might be interpreted on the assumption that enkephalinergic (opiate) receptors are localised on dopaminergic terminals. Assuming that the high affinity Leu-enkephalin binding sites represent postsynaptic receptors for the alleged enkephalinergic neurones, our findings would suggest that these neurones project presynaptically on to dopaminergic nerve terminals. This idea is strengthened by the immunohistochemical demonstration of Leu-enkephalin containing nerve

Table 1 Effects of substantia nigra lesions and intraventricular injections of 6-OHDA on binding of ^{3}H-Leu-enkephalin or ^{3}H-naloxone in rat striatum

Lesions	^{3}H-Leu-enkephalin binding displaceable by morphine (fmol per mg protein)	^{3}H-Naloxone binding (fmol per mg protein)	Dopa decarboxylase activity (nmol per mg protein per h)
Chemical lesion by intraventricular 6-OHDA			
Control animals	162 ± 10	66 ± 3	0.31 ± 0.02
Lesioned animals	126 ± 11*	47 ± 2‡	0.20 ± 0.02†
Variation	−22%	−28%	−33%
Electrocoagulation of the substantia nigra			
Control side	175 ± 11		0.30 ± 0.02
Lesioned side	134 ± 8*		0.19 ± 0.02‡
Variation	−23 ± 2%*		−37 ± 4%

For the chemical lesions the rats received intraventricularly 250 μg of 6-OHDA dissolved in 10 μl of saline containing 2% ascorbic acid. Controls received the same volume of vehicle. Unilateral electrocoagulations of the substantia nigra, pars compacta, were performed under chloral anaesthesia by passing a current of 80 mA for 5 s. Stereotaxic coordinates ($A = +1.8$ mm, $L = 1.8$ mm, $V = -2.3$ mm) refer to the König and Klippel atlas. Animals were killed 6–22 d after placement of lesions. Placement of electrocoagulations was checked histologically. ^{3}H-Leu-enkephalin binding displaceable by morphine was estimated as described in Fig. 1 and typically represented about 1,000 d.p.m. per sample (0.15 mg protein) in controls; triplicate assays varied by less than 5%. Saturable ^{3}H-naloxone binding was estimated on aliquots of the same particular fraction incubated with 3 nM ^{3}H-naloxone (20 Ci mmol^{-1}, NEN Chemicals) alone or in the presence of 1 μM non-radioactive naloxone. DOPA decarboxylase activity was measured, on aliquots of the initial homogenate incubated for 40 min in the presence of 8×10^{-4} M ^{14}C-carboxyl-labelled Dopa (Radiochemical Centre, Amersham). Means ± s.e.m. of five to eight separate experiments, on pools from one to three animals each.

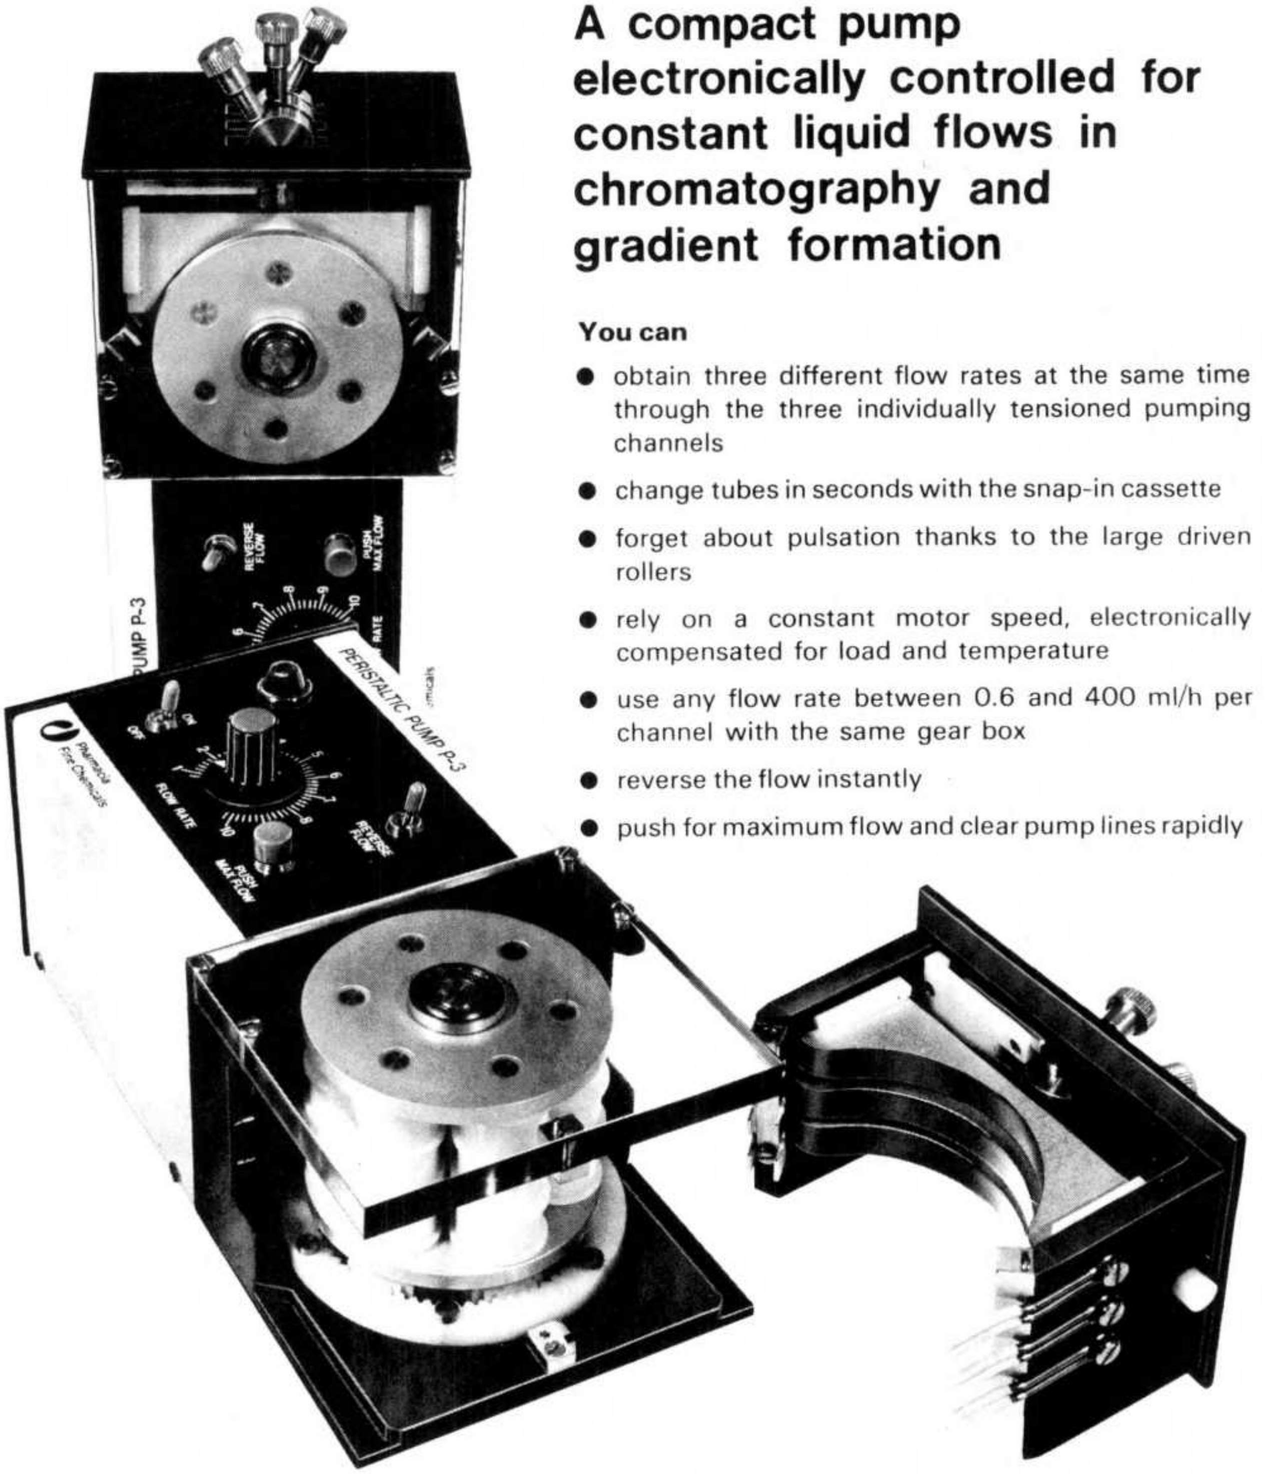
Pharmacia Peristaltic Pump P-3



A compact pump electronically controlled for constant liquid flows in chromatography and gradient formation

You can

- obtain three different flow rates at the same time through the three individually tensioned pumping channels
- change tubes in seconds with the snap-in cassette
- forget about pulsation thanks to the large driven rollers
- rely on a constant motor speed, electronically compensated for load and temperature
- use any flow rate between 0.6 and 400 ml/h per channel with the same gear box
- reverse the flow instantly
- push for maximum flow and clear pump lines rapidly

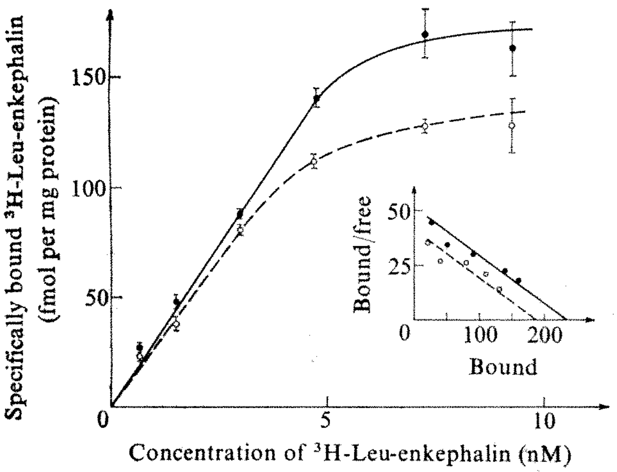

Fig. 2 High affinity binding of ^{3}H-Leu-enkephalin to striatal membranes after unilateral electrocoagulation of the substantia nigra, pars compacta. Rats killed 10 d after placement of the lesions, as described in Table 1. Specifically bound ^{3}H-Leu-enkephalin refers to the binding displaceable by 50 µM non-radioactive Leu-enkephalin. Means ± s.e.m. from triplicate determinations on pooled striata from four animals. Insert: Scatchard plots of the same data. ●, Control side; ○, lesioned side.

terminals in rat striatum[8], by the presence of the peptide in synaptosomal fractions from this region[7,16] and finally, by the effect of morphine and opioid peptides on the release of DA from striatal slices[17,18].

The limited decreases in Leu-enkephalin receptors following our lesions indicate that only a fraction of these receptors in striatum are present on DA neurones. Even after sections of the nigrostriatal bundle at the hypothalamic level, resulting in an extensive depletion (>80%) of striatal DA the decrease in ^{3}H-Leu-enkephalin binding was only 30–40%. This suggests that about one-third of enkephalin receptors in striatum are present on dopaminergic nerve terminals and that non-dopaminergic cells in the striatum might also receive enkephalinergic inputs.

From observations that morphine and endorphins decelerate the K$^+$-induced release of DA slices of rat striatum[17,18], it might be inferred that the effect of enkephalin receptors on dopaminergic neurones could be to modulate DA release in an inhibitory fashion. This would account for the symptoms of a decreased dopaminergic neurotransmission, such as catalepsy, following the administration of morphine or endorphins to rats[19]; the paradoxical increase in DA synthesis might be only a secondary effect like that observed after various treatments resulting in a diminished release of the catecholamine[20,21].

There is already evidence that opiate receptors are also localised presynaptically on sensory fibres of the vagus nerve and the spinal cord[22]. In addition morphine and endorphins reduce the release not only of DA but also of other cerebral neurotransmitters like acetylcholine or noradrenaline[3]. Taken together with our data, these observations suggest that a major function of enkephalins could be to mediate presynaptic inhibitions on a variety of neuronal systems in the central nervous system.

We acknowledge the gift of Leu-enkephalin synthesised by Professor B. P. Roques and his colleagues (Université René Descartes, Paris).

Blowfly ovipositor receptor neurone sensitive to monovalent cation concentration

THE ability of insects to taste salts with sense organs on their legs and mouthparts is well documented. Studies of taste hairs on the tarsi and labella of the black blowfly *Phormia regina* and the bluebottle *Calliphora erythrocephala* have shown that these contain several sensory cells, one of which is a 'salt' or 'type I' primary receptor neurone responding positively to the concentration of monovalent cations[1–6]. I report here some of the receptor characteristics of monovalent cation sensitive neurones found in hair sensilla on the egg-laying apparatus of the sheep blowfly.

Sensory hairs with terminal pores have been identified on the ovipositors of the Australian sheep blowfly *Lucilia cuprina* and the migratory locust *Locusta migratoria*[7,8]. As there is much behavioural evidence to suggest that insects taste their oviposition medium with their ovipositors[9–12], it is likely that the newly described sensilla are the gustatory receptors that mediate such behavioural reactions. In *L. cuprina* these sensilla have been shown, by electrophysiological recording, to contain at least three neurones which respond to stimulation with various chemical solutions[7]. Some gustatory sensilla of caterpillars respond to olfactory stimuli[13], however, and as the ovipositor of the blowfly *P. regina* is known to make directed movements in response to olfactory stimuli[14], it is of interest to know more about the receptor properties of blowfly ovipositor sensilla.

Gravid female *L. cuprina* from our culture of the GL strain were used. Conventional stimulating and recording equipment was used following the procedure of Hodgson *et al.*[15]. The glass micropipette containing the stimulating solution and recording electrode was placed over the tips of each of the 1g–5g sensilla[7] in turn. All of the g sensilla were found to contain a neurone whose rate of firing increased with increasing concentration of applied sodium chloride solutions (Fig. 1 shows a typical result).

Sensillum 1g was the easiest to record from and all results given here were obtained from 1g sensilla. During this work recordings have been made from more than eighty 1g sensilla. The oscilloscope time-base was triggered by the contact artefact, a dual sweep displaying one trace at 10 times the speed of the other, the high speed trace sampling the initial part of the slower trace. This enabled analysis both of the initial rate of firing and also of the adaptation rate. The fast trace was also useful for inspection of the action potential shapes (Figs 1, 2).

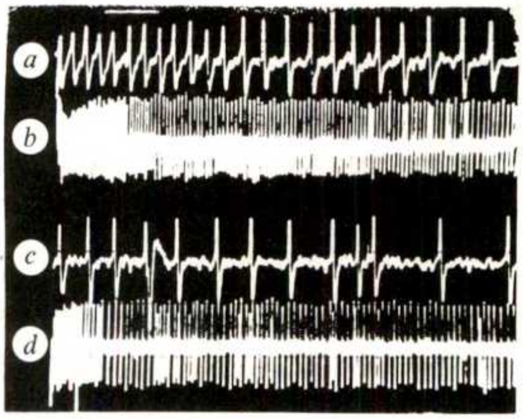

Fig. 1 Effect of NaCl concentration on the initial discharge frequency of the monovalent cation receptor neurone in the 1g sensillum on the ovipositor of *Lucilia cuprina*. *a*, *b*, 1.5 M NaCl; *c*, *d*, 0.15 M NaCl. Traces start at moment of stimulus application. Scale line: 20 ms in (*a*) and (*c*); 0.2 s in (*b*) and (*d*).

Action potentials of three different amplitudes were recorded from the g sensilla on stimulation with salt solutions: small- (1), medium- (2), and large- (3) sized action potentials (Fig. 2). When stimulated with monovalent salts, the labeller taste hairs of *Calliphora erythrocephala* also produce three sizes of impulses which have been tentatively identified as cation, anion and water receptors respectively[16]. In the 1g receptors of *L. cuprina* action potentials from cell 2 are always obtained in response to stimulation with solutions of monovalent cation chlorides, the smaller cell 1 action potentials sometimes accompany cell 2 responses, generally starting to discharge after prolonged stimulation, while the larger cell 3 action potentials are a more rare accompaniment. Responsiveness of the g sensilla varied from fly to fly being influenced by the age and nutritional status of each individual. By comparing the relative stimulating power of a series of cations and anions on single 1g sensilla, replicable results were achieved. Receptor cell 2 was found to be almost equally responsive to 0.15 M solutions of NaCl, NaBr and NaI but much less responsive to solutions of NaF (Fig. 3). The rate of firing of this neurone is largely dependent on the concentration of monovalent cation present in the stimulating solution and, apart from NaF, is not much effected by the anions tested, which included NO$_3^-$ and SO$_4^{2-}$. A range of monovalent cation chlorides were almost equally stimulatory, though the Li$^+$ response had a faster adaptation rate than either Na$^+$ or K$^+$ (Fig. 3).

In contrast to its concentration-dependent responses to monovalent cations, neurone 2 is much less responsive to the divalent cations Ca^{2+}, Mg^{2+} and Sr^{2+} and is totally unresponsive to a range of concentrations of choline chloride. Divalent cations at a concentration of 0.15 M were sometimes stimulatory (Fig. 4) but a 10-fold increase in concentration did not increase the response as it always does with monovalent cations. More details of the responses of 1g sensilla to divalent cations will be published elsewhere.

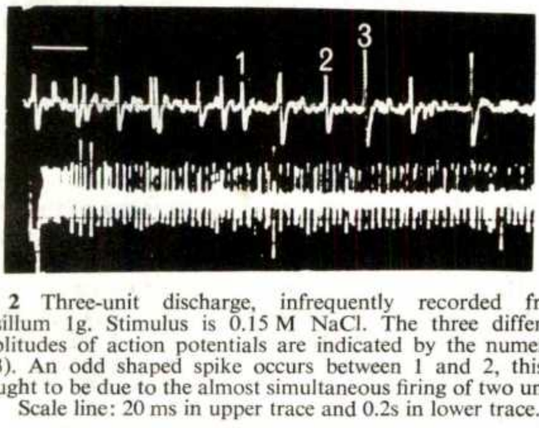

Fig. 2 Three-unit discharge, infrequently recorded from sensillum 1g. Stimulus is 0.15 M NaCl. The three different amplitudes of action potentials are indicated by the numerals (1–3). An odd shaped spike occurs between 1 and 2, this is thought to be due to the almost simultaneous firing of two units. Scale line: 20 ms in upper trace and 0.2s in lower trace.

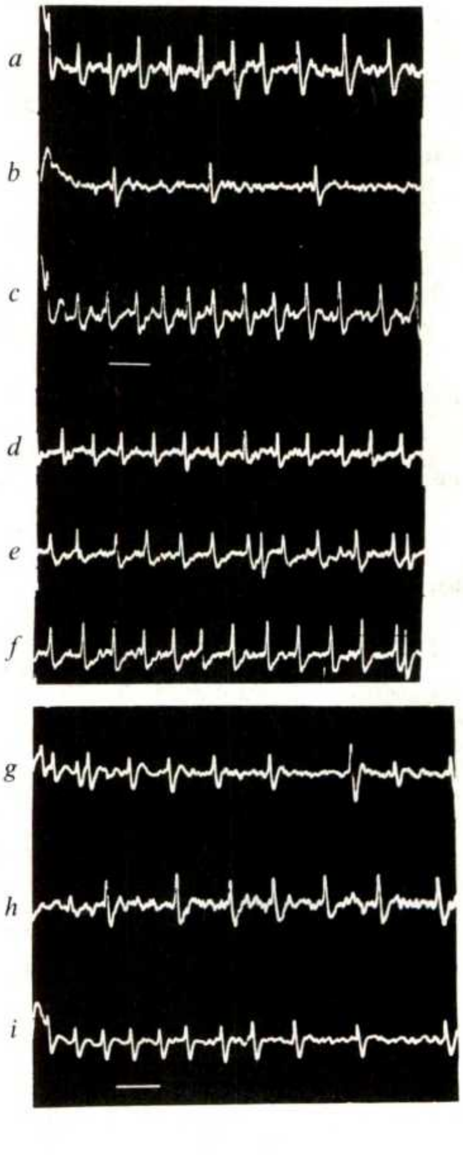
When ranges of NaCl and KCl solutions were tested a logarithmic relationship was found, with the type 2 cell approximately doubling its initial rate of firing for each 10-fold increase in molar concentration of Na$^+$ or K$^+$ ions. Threshold for cell 2 was as low as 0.001 M NaCl in several preparations, which is 100 times lower than was found in the salt receptors of the labellar hairs of *P. regina*[17]. This may reflect the need of the sheep blowfly to identify this salt with its ovipositor receptors when attempting to lay eggs on diluted serous exudates in the wet wool of sheep, sodium being the main monovalent cation of serum.

The cell 2 receptor neurone in the 1g sensillum of the ovipositor of *L. cuprina* is specialised for detection of monovalent cation concentrations. This neurone is very similar to the 'salt' or 'type I' receptor neurones that are so well known from the taste hairs of the blowfly labellum and

Fig. 3 Single-unit responses from two 1g sensilla in response to 0.15 M salt solutions. Scale lines, 20 ms.



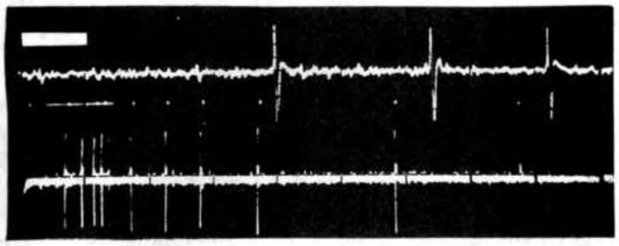


Fig. 4 Single-unit responses from a 1g sensillum to 0.15 M $CaCl_2$ solution. Scale line: 20 ms upper, 0.2 s lower trace.

tarsus[1-6]. This work now adds the ovipositor as the third position in which such receptor neurones are found. The behavioural role of monovalent cation receptors on the sheep blowfly ovipositor is likely to be in the selection of suitable egg-laying sites. When blowflies lay eggs on sheep or on artificial media, probing of the substrate with the ovipositor precedes the deposition of eggs. Locusts and parasitic wasps only lay eggs after the ionic composition of the substrate has been monitored by probing with the ovipositor[9,11]. It is interesting to speculate that alteration of the ion composition on the integument of sheep may influence the egg-laying behaviour of sheep blowflies.

I thank the Australian Wool Corporation for funding this research and Dr C. J. C. Rees for his comments on the manuscript.

Non-cholinergic excitatory transmission to intestinal smooth muscle cells

CONTRACTILE responses of the chicken rectum to stimulation of Remak's nerve and intramural nerves are virtually unaffected by drugs affecting the cholinergic or adrenergic system, suggesting that the remaining response is mediated through excitation of nerves other than cholinergic or adrenergic nerves[1-3]. Using the sucrose-gap method we found excitory junction potentials assumed to be elicited by stimulation of excitatory nerves whose transmitter was unknown[4]. In an attempt to confirm and extend these observations we have studied an electrical change in the smooth muscle membrane, recorded intracellularly, in junctional transmission from excitatory nerves.

The rectum was isolated together with Remak's nerve running parallel to the longitudinal axis of the organ and with its several branches extending to the intestinal wall. This was sectioned lengthwise and mounted in a chamber provided with electrodes which allow Remak's nerve and intramural nerves to be stimulated separately. The membrane potential of smooth muscle cells was measured using conventional glass microelectrodes filled with 3 M KCl and having a resistance of 60–100 MΩ.

Stimulation of the anal cut end of Remak's nerve with single square pulses (0.5 ms duration, at a supramaximal intensity) gave action potentials in cells along the entire surface of the rectum in most preparations. In the majority of cells, action potentials arose from slow depolarisations of the membrane potential which range up to 15 mV from the resting membrane potential (-48.6 ± 2.6 mV, $n=80$) and are interpreted to be excitatory junction potentials (EJPs) elicited by a transmitter released from nerve endings (Fig. 1*a*). In some cells, they fired during the falling phase of EJPs or without any preceding changes in the membrane potential.

The amplitude of the EJPs varied both from preparation to preparation and from cell to cell in any one preparation. Their amplitude also varied with the stimulus intensity. It was possible to evoke subthreshold EJPs by decreasing the stimulus voltage. At any stimulus intensity, stimulation of the oral cut end of Remak's nerve was much less effective in producing the electrical response. These results suggest that the smooth muscle cells in the rectum receive a multiple innervation from the excitatory nerves in varied densities and that the excitatory nerve fibres originate mainly in the ascending fibres of Remak's nerve. In all preparations in which cells giving only an EJP were observed, a train of pulses at frequencies less than 10 Hz facilitated EJPs until the depolarisation reached a level to initiate the action potential (Fig. 1*b*). The observed latency before onset of EJPs was 40–65 ms with a mean of 55.0 ± 2.9 ms (±s.e.). Latency of EJPs was not consistent in cells along the longitudinal axis of the preparation, but it did not significantly vary along the transverse axis; as the microelectrode was moved farther away from the stimulating site, the latency prolonged. The increased latency was up to 20 ms in three preparations after shifting the recording site 20 mm away. EJPs took from 55–100 ms to attain the maximum height after the onset and lasted 600–850 ms.

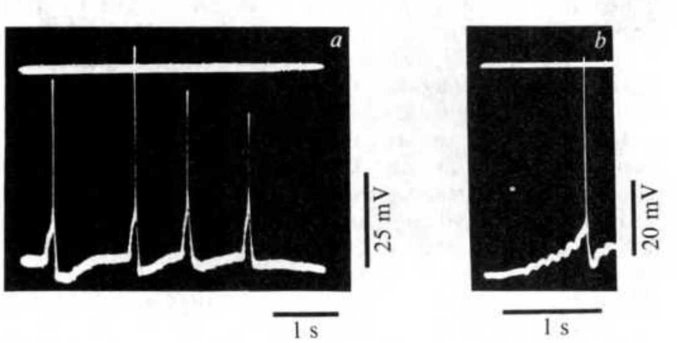

Fig. 1 Intracellular records from smooth muscle cells in the chicken rectum during stimulation with pulses of 0.5 ms duration of Remak's nerve. *a*, Action potentials arose from slow depolarisations of the membrane potential (interpreted to be excitatory junction potentials); *b*, summation of excitatory junction potentials, evoked by repetitive stimulation at 10 Hz, over threshold for initiation of the action potential in another cell.

Field stimulation of intramural nerves (0.1 ms duration) also gave an EJP with latency shorter than those of EJPs elicited by Remak's nerve stimulation. The latencies estimated in EJPs recorded from 30 cells in 8 different preparations varied from 5 to 15 ms with a mean of 9.2 ± 1.2 ms (±s.e.). EJPs in response to Remak's nerve stimulation, but not those to field stimulation, were blocked by hexamethonium (10^{-4} g ml^{-1} or less). Thus, it was apparent that there was ganglionic transmission mediated via acetylcholine receptors of the nicotinic type in the motor pathway from Remak's nerve to the rectum and that the delay of EJPs after the nerve stimulation is largely due to synaptic transmission at the ganglion. Neither atropine nor hyoscience in

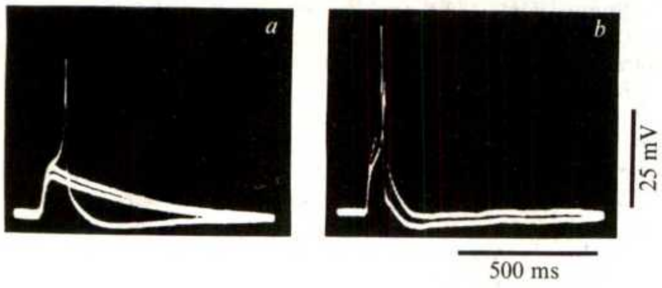

Fig. 2 Effect of atropine on excitatory junction potentials evoked by field stimulation with pulses of 0.1 ms duration at 0.8 Hz. *a*, Control; *b*, 5 min after addition of atropine, 5×10^{-7} l^{-1}, to the bathing solution. Note that the excitatory junction potentials were appreciably potentiated by atropine.

concentrations up to 10^{-6} g ml^{-1} inhibited EJPs evoked by stimulation of the extrinsic and intrinsic nerves and instead these drugs invariably potentiated the EJPs. This effect is illustrated in Fig. 2, where the EJPs are evoked by field stimulation with single pulses at an interval of 1,250 ms before and after application of atropine (5×10^{-7} g ml^{-1}). In these stimulus conditions, facilitation of EJPs was seen in this cell and the third EJP reached the threshold membrane potential to trigger the action potential. In contrast, depolarisation of the first EJP was sufficient for firing the action potential in the presence of atropine. Physostigmine at between 10^{-9} and 10^{-7} g ml^{-1} did reduce the EJPs without change in the membrane potential. Drugs affecting adrenergic functions had no effect on the EJPs. Tetrodotoxin 10^{-7} g ml^{-1} abolished the electrical responses to field stimulation as well as Remak's nerve stimulation.

It is very likely that neurones directly involved in generation of the EJPs are neither cholinergic nor adrenergic. It is possible that there is a muscarinic mechanism by which the motor transmission to the smooth muscle cells is inhibited.

Calcium transients in frog slow muscle fibres

MANY muscles in the frog contain slow as well as twitch muscle fibres, which differ in their innervation, electrical and contractile properties and fine structure[1]. Slow fibres give graded slow contractions with nerve stimulation, and can maintain a prolonged contracture when depolarised. There is evidence that contractile activation in slow fibres is mediated by a rise in myoplasmic calcium concentration[2], but it is not clear whether this calcium originates from the sarcoplasmic reticulum, as in twitch fibres, or enters the fibre from the external solution[1,3–5]. We have used the calcium indicator dye arsenazo III (refs 6–9) to follow changes in intracellular free calcium concentration occurring during depolarisation of slow fibres, and find that the membrane potential dependence of these calcium transients in slow fibres is very similar to that observed in twitch fibres[9]. The time courses of the calcium transients in slow fibres are, however, very much slower than in twitch fibres[9,10], and may be a major factor in determining the time courses of tension development and relaxation.

Experiments were performed on the pyriformis muscle of *Rana temporaria*[11], using a bathing solution of composition (mM); NaCl, 120; KCl, 2; $CaCl_2$, 12; *p*H, 7. Intracellular calcium changes with arsenazo III were measured as previously described for twitch fibres[8,9]. Briefly, by cutting away the lower part, the muscle was reduced to a thin sheet of fibres which was stretched until contraction was practically abolished. Fibres were impaled with two electrodes, about 150 μm apart, for voltage recording and dye injection. Slow fibres were identified by their inability to generate action potentials and their slow electronic time constant when tested with current pulses applied through the dye pipette. The membrane potential was held at −100 mV by passing a hyperpolarising current through the dye pipette, and this served also to slowly inject arsenazo III into the fibre. Changes in light absorption of the dye were monitored by focusing light from a 50-W bulb on to a spot of about 80 μm diameter between the pipettes, and measuring the transmitted light at wavelengths of 532 and 602 nm using two photomultipliers and interference filters. The light absorbance of arsenazo III changes in opposite directions at these wavelengths in the presence of calcium, and by subtracting the signals from the two photomultipliers a record is obtained which gives a quantitative measure of changes in free calcium concentration, but is little affected by movement artefacts[8,9].

Changes in intracellular free calcium concentration produced by depolarising pulses are shown in Fig. 1. The size of the calcium transient is a graded function of membrane potential, and the rates of increase and decay of calcium concentration are much slower than in twitch fibres[9,10]. The decay time constant measured in six fibres varied between 0.6 and 4 s, and the maximum rate of increase in free calcium concentration in 10 fibres was 0.045 μM ms^{-1}

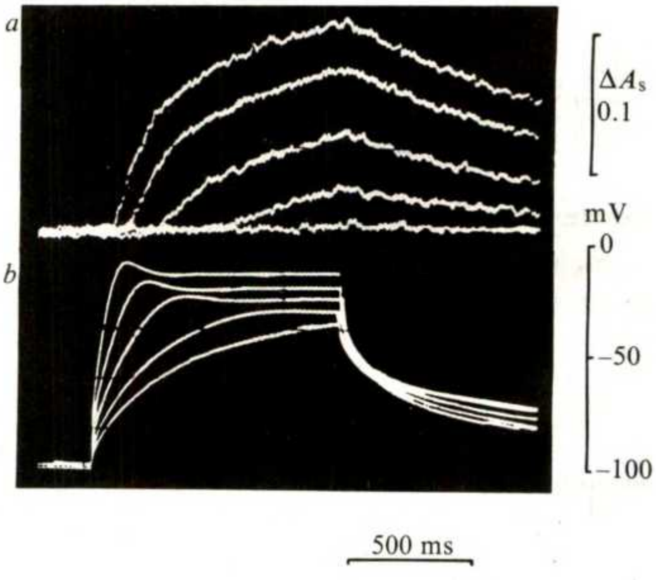

Fig. 1 Light absorbance records from a fibre injected with arsenazo III, showing responses to depolarising pulses of different amplitudes. *a*, Light absorbance changes at the wavelength pair 532–602 nm. *b*, Membrane potential. The light absorbance traces were recorded through a low-pass filter of time constant 10 ms, and the calibration (ΔA_s) gives the change in absorbance as a fraction of the total absorbance of the injected dye at a wavelength of 532 nm. An upward deflection indicates an increase in free calcium concentration, and ΔA_s of 0.1 is equivalent to an increase in free calcium of 2 μM (ref. 9). Five superimposed sweeps are shown. Stimuli were constant current pulses of 1 s duration and varying amplitudes. Temperature 7 °C.

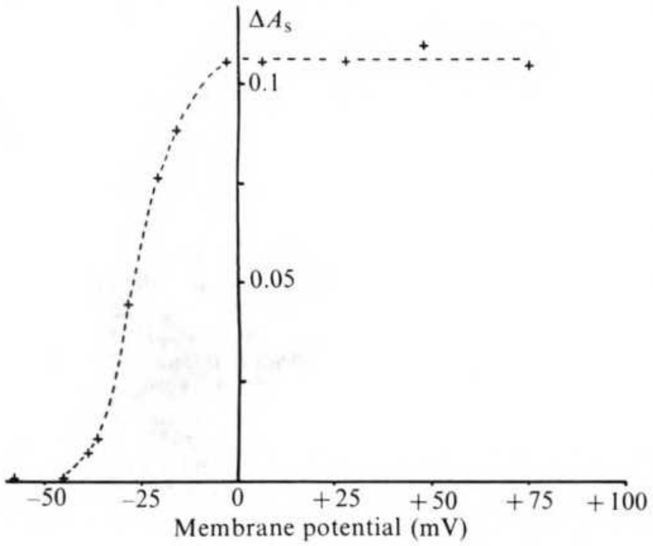

Fig. 2 Relationship between calcium response and membrane potential recorded in one fibre using depolarising pulses of 100 ms duration. Abscissa: membrane potential during pulse. Ordinate peak change in standardised light absorbance (ΔA_s) at the wavelength pair 532–602 nm. The fibre was voltage clamped using the dye pipette as a current-passing electrode, and the membrane potential was held at −90 mV between pulses. Temperature, 7 °C.

±0.025 (mean ±s.d.), when depolarised to a potential above that required to obtain a maximal response (compare Fig. 2). Corresponding values for twitch fibres are 50 ms and 0.95 μM ms^{-1} (ref. 9). The rise in calcium concentration during depolarisation shows two phases: an initial rapid increase, followed by a transition to a much slower rate of rise. This is probably a property of the calcium release mechanism, and is unlikely to be due to any nonlinearity in the recording system as the transition occurs at different calcium concentrations for different sized pulses, and the rate of calcium uptake is probably too slow to account for the transition.

To examine the relationship between membrane potential and calcium release the membrane potential was clamped at the measuring spot, and the peak size of the calcium transient measured for different amplitudes of 100 ms depolarising pulses (Fig. 2). The calcium transient is a sigmoid function of membrane potential over a range of approximately −45 to 0 mV, and the relationship is very similar to that found in twitch fibres[9]. With large depolarisations (+75 mV) the calcium response is not depressed, which suggests that the entry of external calcium is not important in the generation of the calcium transient, since the driving force for calcium entry would be reduced at this potential[9,12].

The role of external calcium was further studied by buffering the calcium concentration in the bathing solution at $<10^{-7}$ M with 1 mM EGTA and 5 mM $MgCl_2$. We found no changes in the calcium transients produced by 100-ms depolarising pulses in this solution: mean response sizes produced by supramaximal depolarising pulses in 12 mM calcium and calcium-free solution were respectively 2.0 μM ±1.1 ($n = 9$) and 1.4 μM ±0.4 ($n = 4$), while the relationship between membrane potential and calcium release and uptake remained the same (Fig. 3*c*,*d*). During a prolonged depolarisation, however, the calcium response is considerably affected by removal of calcium from the bathing solution, and the response becomes transient, rather than maintained (Fig. 3*a*, *b*). This effect is well known from studies of contractile tension[13], and might result from either an action of external calcium on the activating sites in the T-tubule membrane, or from the absence of a calcium influx which is required to maintain the intracellular calcium level. To test the importance of calcium influx during maintained contractures in 12 mM calcium, we gave a step depolarisation to +80 mV during prolonged depolarisations to +20 mV. This additional depolarisation should have reduced any calcium influx, but all experiments showed a small rise in intracellular calcium concentration, rather than a fall.

These experiments are in agreement with other work[5] in demonstrating than an influx of external calcium is not directly involved in contractile activation in slow fibres, and the striking similarity in the relationships between membrane potential and calcium response for slow and twitch fibres supports the view that activation in slow fibres occurs by the same mechanisms as in twitch fibres[4,5,13]. External calcium is, however, important in the maintenance of prolonged contractures, possibly by affecting the rate of inactivation of the activating sites within the T tubules[13,14]. The slow rates of increase and decay of intracellular calcium in slow fibres may arise simply as a consequence of the relative scarcity of sarcoplasmic reticulum and triads[15–17], and are probably major factors in determining the rates of contraction and relaxation in slow muscle. Our values for the rate of decay of the calcium transient are in good agreement with measurements of tension relaxation[1,5,18], but the slow shortening velocity of the myofibrils[2] may also be an important factor in determining the rate of tension development.

Fig. 3 Effects of removal of external calcium on the calcium responses to prolonged (*a* and *b*) and short (*c* and *d*) depolarising pulses. In each record the fibre was depolarised from −100 mV to +20 mV during the times indicated by the bars, and all records were obtained from different fibres. Ringer solution containing 12 mM $CaCl_2$ (plus 120 mM NaCl and 2 mM KCl) was used in *a* and *c*, while in *b* and *d* the solution was (mM); NaCl, 120; KCl, 2; $MgCl_2$, 5; EGTA, 1; *p*H 7. Traces show changes in light absorbance at the wavelength pair 532–602 nm, and the calibration bars are $\Delta A_s = 0.5$ for *a* and *b*, and $\Delta A_s = 0.1$ for *c* and *d*. In *b* a small shift of the baseline occurred due to movement of the fibre. Temperature, 7.5 °C.

Induction of experimental allergic neuritis with a peptide from myelin P_2 basic protein

EXPERIMENTAL allergic neuritis (EAN) is an autoimmune demyelinating disease of the peripheral nervous system (PNS) produced in animals by injection of homogenates of PNS tissue[1] or PNS myelin[2] emulsified with Freund's complete adjuvant. Although it has been produced in such species as rabbits[1], guinea pigs[3], and mice[3], the neuritogenic determinant has not been identified. In experimental allergic encephalomyelitis (EAE), the central nervous system (CNS) counterpart of EAN, the encephalitogen is the myelin basic protein[4]. PNS myelin has two basic proteins, P_1 and P_2[5], and the latter has been suggested to be the neuritogen[2]. In attempts to induce the disease with intact P_2 (refs 6–9), mild symptoms of EAN were occasionally produced, but these were inconsistent. P_2 was implicated as the neuritogen when circulating lymphocytes of animals with EAN induced by injection of whole PNS myelin[10] were found to be sensitised to P_2 but not P_1. Physicochemical studies of P_2 have demonstrated a very stable β structure in aqueous solution[11]. Because the conformation is likely to differ in solution and in intact myelin, it is likely that the r ogenic determinant(s) are altered. We have, therefore, teste ides derived from the protein in order to minimise alter n of any neuritogenic determinant by extraneous port s of the intact molecule. We have identified a neuritogenic determinant within P_2—within a peptide representing the NH_2-terminal 21 amino acids of P_2.

P_2 (55 mg) was digested with cyanogen bromide (CNBr) (ref. 12) (in 3.0 ml 70% formic acid) and the resultant peptides were separated by chromatography on a column (1.5 × 69 cm) of Sephadex G-50. The column was equilibrated and eluted with 0.1 M acetic acid at 35 ml per h; 3.0 ml fractions were collected. Two main fragments were isolated and designated fragment I (fractions 10–35) and fragment II (fractions 38–43). Fragment II had a blocked NH_2-terminal and 21 amino acids. Fragment I comprised the bulk of the remaining molecule. The isolation and characterisation of the CNBr peptides will be described in detail elsewhere.

When tested for disease in rabbits, fragment II produced histological lesions characteristic of allergic neuritis—perivascular infiltration of mononuclear cells and demyelination (Table 1). The two rabbits receiving 300 µg each of fragment II did not develop clinical symptoms. Two of the three receiving 500-µg doses developed a general weakness and weight loss while the third developed marked clinical symptoms including ataxia and severe weakness of the hind quarters. The symptoms in this rabbit and the histological lesions in all the affected rabbits were similar to those observed when either whole PNS homogenates[1] or purified PNS myelin[2] is the inducing agent. The CNS remained essentially unchanged in these animals. Occasional lesions were observed in the spinal cord in the area of the root entry zones but these were interpreted as infiltration of cells responding to PNS myelin and overflowing into the adjacent spinal cord tissue.

Rabbit OR4 (Table 1) also had a few lesions along the ventral fissure of the lumbar cord. This animal had such an overwhelming inflammation and acute infiltration of cells throughout the PNS, especially in the dorsal root ganglia, that some spinal cord involvement extending beyond the area of the root entry zone was not surprising. Because this was the only area involving CNS tissue and was mild in comparison with the PNS involvement, it was interpreted as a nonspecific consequence of the cell-mediated response to the neuritogen, a phenomenon similar to that reported by Wisniewski and Bloom[14].

When fragment I was injected into rabbits (1 mg per animal), some histological lesions were observed, suggesting the possibility of additional neuritogenic determinant(s) in the remainder of the molecule. This latter observation is being further investigated.

Thus it seems that P_2 contains at least one determinant for EAN in the rabbit. Apparently this neuritogenic determinant is inaccessible in the isolated intact protein, probably as a result of the non-native β structure. When removed from the bulk of the protein, fragment II must assume a conformation which approximates that found in the intact myelin.

Since P_1 can also cause disease[8] the question of contamination of P_2 or fragment II with the encephalitogenic P_1 protein must be considered. In our hands, when rabbits are sensitised with P_2, no histological lesions are noted in either the CNS or PNS and only rarely are a few transitory clinical symptoms observed[7]. Thus, our P_2 preparation does not seem to be contaminated with P_1. It is even

Table 1 Induction of EAN* in rabbits by fragment II†

Animal no.	D (ı	Clinical symptoms (day of onset)	Day of killing	Histology‡			
				Perivascular cuffing		Demyelination	
				CNS	PNS	CNS	PNS
R 30	300	—	27	0	+/−	0	+/−
R 31	300	—	27	0§	+	0	+
OR 4	500	Weight loss, ataxia, and hind quarter weakness (19)	20	+/− ‖	+ +	+/− ‖	+
OR 8	500	Weight loss and weakness (23)	28	0	+	0	+
OR 9	500	Weight loss and weakness (21)	28	0	+	0	+

*Antigen was dissolved in saline and emulsified with an equal volume of Freund's complete adjuvant (H37 ra) containing 1 mg ml^{-1} *Mycobacterium tuberculosis*. Each rabbit received 0.1 ml in each of its four footpads (total 0.4 ml per animal).

†Fragment II, the NH_2-terminal 21 amino acid peptide from bovine peripheral nerve myelin P_2 basic protein.

‡The system used to grade the histology is similar to that of Alvord and Kies[12]; the Signs used are: 0, no abnormality; +/−, a few small foci of perivenular leukocytes within neuraxis; + +, large and numerous foci of perivenular leukocytes with neuraxis.

§Two foci of a few mononuclear cells in the white matter of the lumbar cord were observed.

‖Refers to entire neuraxis. There were also some + + lesions in the ventral fissure of the lumbar spinal cord with subpial demyelination. These lesions occasionally extended into the deep white or grey matter and were also demyelinative.

more unlikely that the fragment II preparation isolated from P_2 is contaminated since it is processed further after CNBr cleavage by column chromatography and/or paper electrophoresis.

EAN is the experimental disease model for one of the most common human peripheral neuropathies, infectious polyneuropathy of Guillain-Barré. The experimental disease is very similar in every regard to the human disease[15] and cells sensitised to P_2 have been found in patients suffering from this disorder[16]. Any understanding and/or treatment of the experimental disorder may prove extremely useful in devising potential treatment for the human disease.

Myelination of mouse axons by Schwann cells transplanted from normal and abnormal human nerves

In mouse nerve iso- and allografts, Schwann cells transplanted from the donor animal survive, multiply within the graft and, eventually, ensheath axons regenerating from the host nerve[1-3]. This demonstration of the persistence of donor cells in nerve grafts has made possible the *in vivo* study of cell interactions in genetically-determined animal neuropathies. By combining normal and abnormal nerves, each originating from different strains of mice, a primary Schwann cell abnormality has been demonstrated in Trembler[3] and Quaking[4] mutant mice while axonal factors seem to be responsible for changes in the spinal roots of dystrophic mice[5,6]. We report here the successful transplantation into immunologically-suppressed mice of human Schwann cells from control patients and from the sural nerve of a child with metachromatic leukodystrophy. Metachromatic leukodystrophy (MLD) is a human autosomal recessive disease due to aryl sulphatase deficiency and characterised by degeneration in the central and peripheral nervous systems with intracellular accumulations of metachromatic granules[7,8].

Control human sural nerves were obtained from limbs amputated because of peripheral vascular disease or trauma and from a diagnostic biopsy taken from a 10-yr-old child investigated for muscle weakness. Sections obtained from these control nerves showed no evidence of neuropathy by light microscopy. Segments of MLD nerve were obtained from a sural biopsy of a 10-yr-old girl with a 5-yr history of progressive neurological deterioration and peripheral neuropathy. The diagnosis of MLD was documented by two nerve biopsies, both of which showed the characteristic metachromatic material within Schwann cells.

Fascicles 5 mm in length were removed from the control human nerves and, in 23 normal C57 BL/6J mice, grafted between the stumps of left sciatic nerves transected at mid-thigh level. Nerve from the patient with MLD was grafted in identical fashion into 12 other C57 BL/6J mice. All grafts were secured by 10-0 nylon sutures placed through the connective tissue surrounding the nerve. These procedures were carried out in aseptic surgical conditions within 3 h of limb amputation or biopsy, donor nerves being kept in cold Ringer's solution before grafting.

To prevent rejection of the xenografts, anti-lymphocytic serum (ALS) was prepared by injecting rabbits twice with a suspension of 10^9 living thymocytes from C57 BL/6J mice[9] and administered subcutaneously to the host animals in doses of 0.5 ml twice weekly. At intervals from 10 days to 3 months after grafting, host mice were killed by systemic perfusion of fixative containing 1.5% glutaraldehyde, 0.05% formaldehyde and 0.5% calcium chloride in 0.08 M Sorensen's phosphate buffer. Cross sections from the proximal and distal sciatic nerve stumps of the host and from the mid-portion of the graft were examined by phase and electron microscopy.

Soon after grafting, nerve fibres in the graft and distal stumps of the grafted nerves underwent characteristic changes of Wallerian degeneration but there was no rejection of the graft. From 3 weeks after grafting, there were increasing numbers of regenerated myelinated and unmyelinated nerve fibres within the graft and distal nerve stumps (Fig. 1*a*, *b*). Although the initial stages of regeneration and myelination were similar in grafts originating from control and MLD nerves, numerous metachromatic granules were observed within Schwann cells in the MLD grafts by 2½ months after grafting (Fig. 2*a*, *b*).

Schwann cells in the grafted segments of these regenerated nerves could have originated either by migration from the proximal nerve stump of the host or from Schwann cells indigenous to the graft. In the first instance, Schwann cells in the regenerated graft would be mouse Schwann cells; in the second, human Schwann cells would ensheath mouse axons. Although large numbers of Schwann cells do not migrate from the proximal stumps of host nerves into mouse isografts or allografts during regeneration[1-3,10], it is conceivable that these cells might behave differently in xenografts. Thus, to identify cells of mouse and human origin in these regenerated nerves, ALS was discontinued

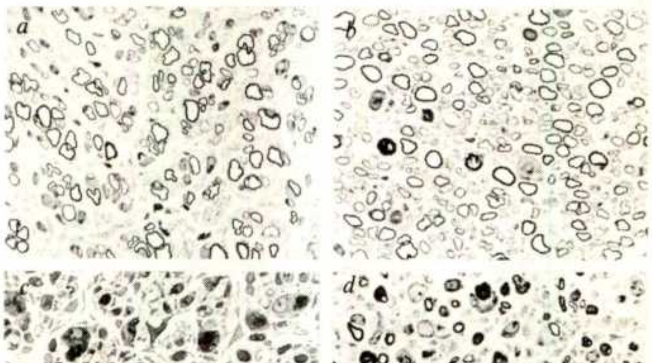

Fig. 1 Cross section of grafted segments of distal stumps of human sural nerve to mouse sciatic nerve xenografts. *a, b,* 10 weeks after grafting a segment of control human sural nerve into the sciatic nerve of an immune-suppressed mouse, axons have regenerated from the proximal stump into the graft and distal stump. At both these levels of the same regenerating nerve, there are abundant myelinated fibres. *a,* Graft; *b,* distal stump. 4 weeks after stopping ALS and 10 d after the transfer of immune cells to the host animals, a 6-week-old regenerated graft is rejected. The rejection reaction is indicated in the graft (*c*) by myelin debris, increased cellularity and a complete loss of myelinated fibres. In the distal stump of the same nerve (*d*) many myelinated fibres are preserved although some show signs of Wallerian degeneration, presumably due to axonal damage at the level of the graft. (Phase contrast photomicrographs (× 660).

in a group of mice from 4 weeks to 2 months after grafting. From 2 to 3 weeks after discontinuation of ALS these mice also received intravenously 10^8 lymphoid cells prepared from the spleen and lymph nodes of syngeneic mice hyper-immunised against tissue antigens by intravenous injection of 10^7–10^8 human leukocytes twice weekly for 3 weeks. This cell transfer was used to abrogate the xenograft acceptance in the recipient animal and to ensure a more rapid rejection of all 'foreign' cells[11]. Although discontinuation of ALS will cause xenograft rejection, the additional immune cell transfer permits a more accurate timing of rejection for histological studies.

Ten mice in which ALS had been discontinued were examined for 4–81 d after immune cell transfer. On d 8, early rejection was indicated by small accumulations of mononuclear cells in the nerve grafts. By d 10, there was an intense reaction in the grafted segments (Fig. 1*c*). Schwann cells of both myelinated and unmyelinated fibres were surrounded, penetrated and eventually replaced by mononuclear cells (Fig. 3*a*). Perineurial fibroblasts were also rejected in the grafts. During this acute phase of rejection, some axons became totally denuded of Schwann cells and were surrounded only by basal lamina (Fig. 3*b*).

During graft rejection, many fibres in the distal stumps remained myelinated, showing that the continuity of their axons was preserved. But, a certain number of axons must have been interrupted, presumably in the graft, because fibres undergoing Wallerian degeneration were observed in distal stumps of the same nerves (Fig. 1*d*).

In two animals allowed to survive the period of rejection for more than 2 months, the segments of nerves at the site of the original graft again contained large numbers of myelinated fibres. Presumably, migration of mouse Schwann cells from the stumps of the host nerves was responsible for the reappearance of these myelinated fibres. This migration may have been facilitated and guided by the axons and empty basal lamina which survived rejection.

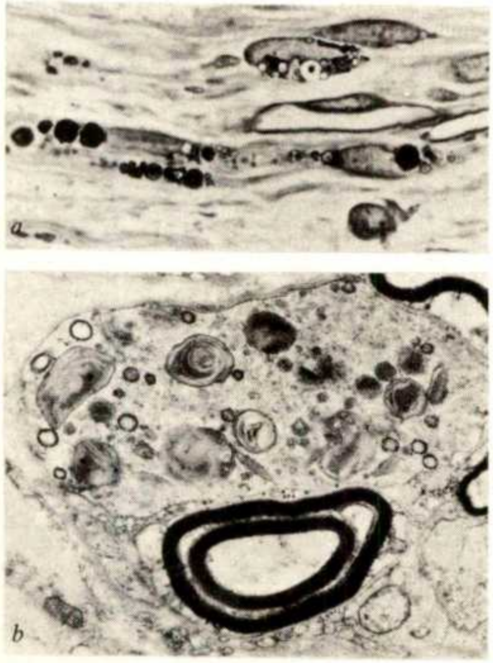

Fig. 2 Segments of human MLD sural nerve grafted into mouse sciatic nerve. *a*, After 2½ months, axons from the mouse nerve stump have regenerated into the graft and are associated with Schwann cells which contain myelin ovoids and numerous small granules. These granules, which stain metachromatically with cresylviolet, were confined to the graft and were not observed in the proximal and distal nerve stumps. (Longitudinal section, phase micrograph (× 1,200). *b*, Lamellated and amorphous intracellular inclusions are present in the mid-portion of a human MLD to mouse sciatic nerve graft. (Electron micrograph (× 13,500).

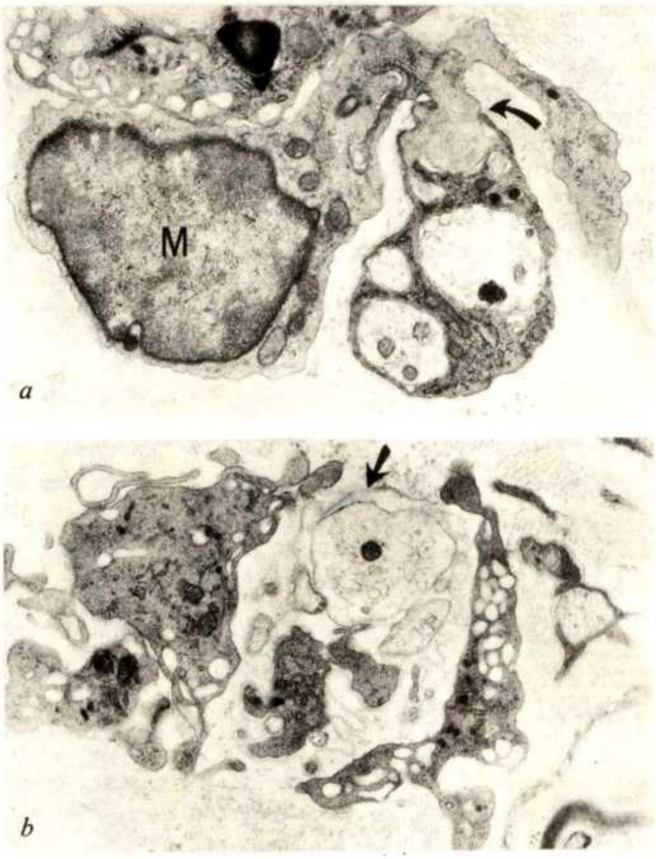

Fig. 3 Details of rejection of the nerve graft shown in Fig. 1*c*. A cytoplasmic process from a mononuclear cell (M) has partially penetrated the basal lamina of an unmyelinated fibre (arrow). *b*, One large and several small axons persist within the basal lamina (arrow) of a rejected Schwann cell. Macrophage processes are present on both sides of the residual basal lamina. (Electron micrograph (× 9,800).

The selective rejection of most of the sheath cells in the regenerated grafts establishes that the grafted segments of these nerves still contained fibroblasts and Schwann cells foreign to the mouse. Thus, regenerated nerve fibres within the grafts must represent a combination of mouse axons and human Schwann cells. The presence of metachromatic granules in grafts originating from the sural nerve of a patient with MLD 2½ months after grafting into mouse nerves is additional evidence of the presence of human Schwann cells in the regenerated xenografts. This finding also suggests that the grafted MLD sheath cells continue to be deficient in aryl sulphatase during nerve regeneration in the mouse and may be unable to utilise this enzyme from the host.

These studies in nerve xenografts have shown that (1) human Schwann cells can ensheath and myelinate regenerating mouse axons; (2) the perineurium of the regenerated grafts contain human fibroblasts; (3) during rejection of regenerated grafts, the immune response is directed against fibroblasts as well as Schwann cells of myelinated and unmyelinated fibres; axons may be affected secondarily[12]; (4) if, after regeneration across a graft, the xenogenic sheath cells are rejected, they can be replaced by the host's own Schwann cells which migrate along the re-established pathways formed by axons and basal lamina tubes; (5) human neuropathies may be reproduced by transplanting fascicles from the patient's nerve into immune-suppressed animals.

Thus, the present *in vivo* combinations of human and animal cells may help in the investigation of biological mechanisms and permit a better definition of the role of axons and Schwann cells in normal and pathologic human nerves. Human Schwann cells transplanted into laboratory animals are now amenable to experimental manipulations which may include enzyme replacement and immunological studies.

Drs Peter Humphreys, Stanley Rothman and George Karpati kindly provided biopsies for transplantation. We thank J. Trecarten and M. Attiwell for technical assistance. Two mechanisms for positive inotropism of low-K Ringer solution in bullfrog atrium

IT has long been known that a reduction of K concentration in external fluid immediately potentiates the twitch contraction of frog heart[1]. Microelectrode studies[2,3] have revealed a hyperpolarisation of the membrane and a prolongation of the action potential, which was thought to be a cause of the potentiation of contraction. But, when the muscle is soaked in K-depleted fluid the membrane Na/K ATPase and the activity of the Na pump are inhibited[4] and Na ions progressively accumulate within the cell[5]. In myocardium, the accumulation or rise of $[\mathrm{Na}]_i$ produces a secondary increase of $[\mathrm{Ca}]_i$ due to Na–Ca exchange diffusion and the consequent positive inotropic effect[6,7]. Thus, Ehara[8] has demonstrated the presence of a delayed potentiating effect of low-K Ringer solution possibly due to Na-pump inhibition in the frog ventricle as well as its immediate inotropic effect. We have tried to clarify further the nature of these inotropic actions. We show here that, in the frog atrium, augmentation of Ca-inward current (I_{Ca}) and increase of I_{Ca}-independent tonic tension, related to Na–Ca exchange, are responsible for the immediate and delayed inotropic effects under voltage clamp, respectively.

Thin muscle bundles (diameter 0.4–0.5 mm) isolated from the right atrium of the bullfrog, *Rana catesbiana,* were used. The membrane potential, current and tension were measured in voltage-clamped and unclamped conditions with the conventional double-gap method[9], in which the width of the central test chamber was about half (0.3–0.4 mm) of the space constant[10]. With this apparatus gap action potentials (AP) of more than 100 mV were commonly obtained and the short circuiting factor was greater than 0.8 for both gaps. The central chamber was initially perfused with normal Ringer containing 2.5–4.0 mM K until the twitch tension became steady, and then the solution was replaced with low-K Ringer (0–0.16 mM K). All experiments were performed at a constant temperature, 16–17 °C.

In unclamped conditions, K-depleted Ringer solution produced biphasic positive inotropic effects in some atrial preparations (Fig. 1*a*) but not as often as in the ventricle[8]. The partially fused effects seemed much faster (five to six times) in the former than in the latter, probably due to thiness of the muscle fibres and scattering of the bundles in the atrium. The immediate and late potentiations, however, could be discriminated in the presence of ouabain (10^{-6} M, Fig. 1*c*) which eliminated the late potentiating effect. The initial inotropic effect was accompanied by a hyperpolarisation of the membrane, a rise in threshold, and an increase in amplitude and duration of AP. During the late inotropic effect, on the other hand, a gradual depolarisation plus lowering and prolongation of AP were produced together with a gradual increase of membrane slope resistance (Fig. 1*d*). Automaticity was often elicited during this later phase (Fig. 1*b*), and augmented twitch contraction showed a special pattern of fast tension development and slow relaxation. In the final depressive stage of contraction, the basal tension increased and the AP was further suppressed; and after a few hours of soaking in K-depleted Ringer, addition of K ions (4 mM) produced recovery, and hyperpolarisation instead of depolarisation of the membrane. This suggests activation of the electrogenic Na pump (Fig. 1*e*).

Voltage-clamp studies during the initial 2–5 min after K-depletion disclosed that considerable potentiation of contraction still occurred in response to constant depolarising pulses. The fast Na-inward current (I_{Na}), though not accurately measurable, was virtually unchanged during this period (see Fig. 2*c*), however the slow inward current in the presence of tetrodotoxin (TTX) ($5\times10^{-7}\,\mathrm{g\,ml^{-1}}$) and the Ca-inward current (I_{Ca}) isolated in Na-free sucrose Ringer solution were markedly prolonged after K-depletion. The

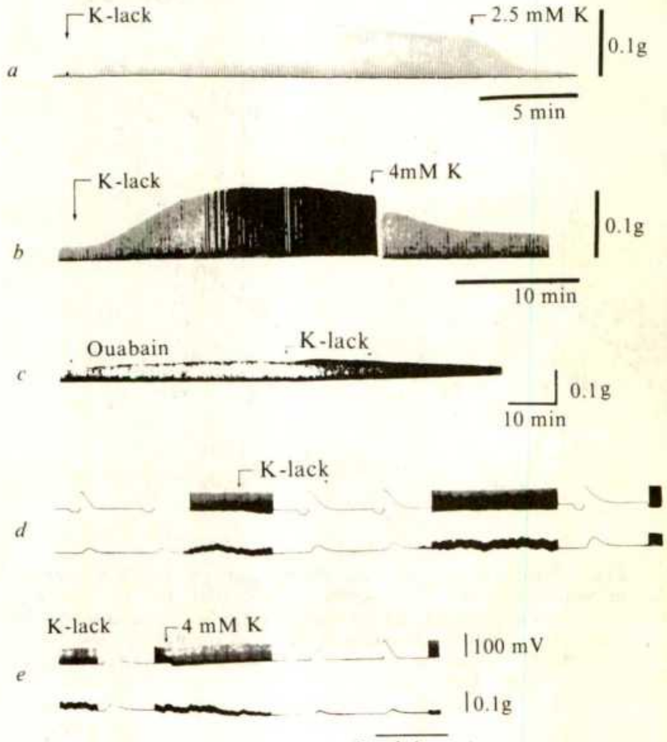

Fig. 1 Immediate and delayed positive inotropic effects of K-free Ringer on bullfrog atrium. *a,* Biphasic inotropic responses. *b,* Monophasic inotropic response with arrhythmia at later phase. *c,* Effects of K-depletion in the presence of ouabain (10^{-6} M). *d,* Effects of K-depletion on membrane potential and contractility. A hyperpolarising pulse was given before each action potential. *e,* Effects of administration of m 4 mM K at the depressive stage 5 h after K-depletion. Note increase of membrane slope resistance and hyperpolarisation followed by gradual depolarisation in (*c*) and appearance of hyperpolarisation after administration of K in (*e*).

prolongation was mainly due to a long delay of the inactivation process (Fig. 2*a*,*b*). The leaky inward and outward currents decreased as expected (Fig. 2*c*). But, the voltage–current relationships obtained in Na-free Ringer solution, in which the anomalous rectification was completely eliminated, confirmed the initial enhancement of I_{Ca} after K-depletion (Fig. 2*d*). The experiments also clarified a concomitant augmentation of the I_{Ca}-dependent tension (not shown). These observations clearly indicate that the initial inotropic effect of K-depletion is not simply dependent on prolongation of the AP due to decrease of leaky currents but also on an augmentation of I_{Ca} and I_{Ca}-dependent tension.

Meanwhile, during the late inotropic phase more than 10 min after K-depletion, the fast and slow inward currents were gradually depressed (not shown). The I_{Ca}-dependent phasic component of tension diminished, while the I_{Ca}-independent tonic component was markedly augmented (Fig. 3*a*). Voltage–current relationships during these later phases also showed a decrease of the slow inward current (Fig. 3*b*) as well as the isolated I_{Ca} (Fig. 2*d*). Depression of the leaky inward and outward terminal currents persisted. Those characteristics may well account for the typical configuration of the action potential: depressed overshoot and plateau followed by a long tail (Fig. 1*e*). The marked reduction of electrogenic outward current by inhibition of Na pump observed in sheep Purkinje fibres[11] was not seen in the frog atrium, although a presence of an electrogenic potential was noticed in the final depressive stage of contraction. Thus, the principal cause of the late positive inotropic effect of low-K solution was augmentation of I_{Ca}-independent tonic tension and prolongation of the action potential.

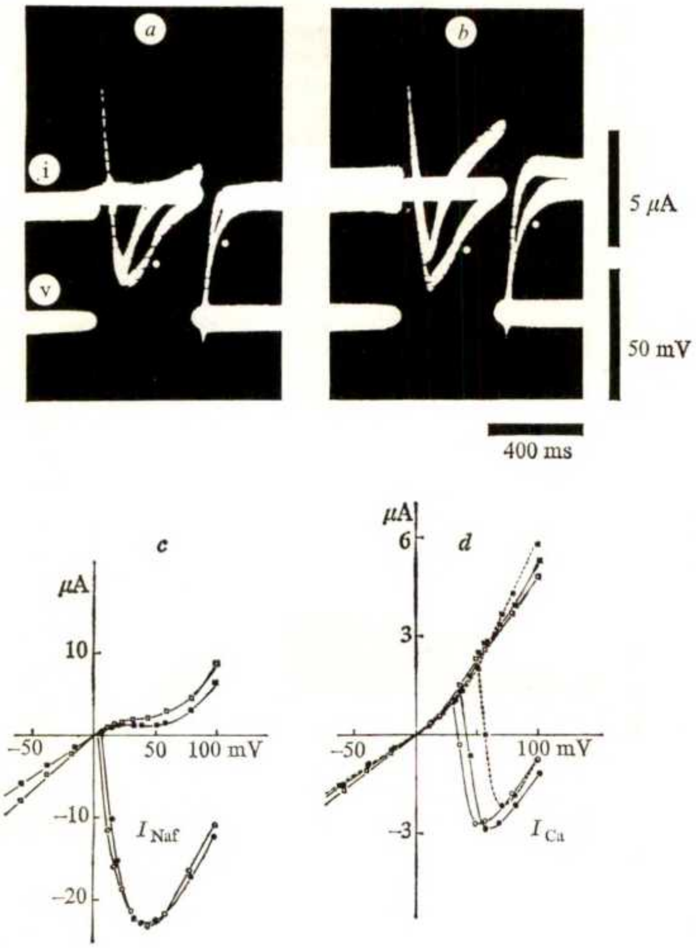

Fig. 2 Initial effects of K-depletion on membrane currents in voltage clamp. The membrane potential was held at the gap resting potential and rectangular pulses were applied at intervals exceeding 10 s. *a*, Superimposed records of Ca-inward currents before, and 5 min after K-depletion (○) in response to the same depolarising pulses (47 mV, 400 ms) given from the holding potential level (−70mV). Data were obtained in Na-free sucrose Ringer solution throughout. *b*, Similar superimposed records taken 6 min after K-depletion (○) and 2 min after washing with normal Ringer solution (4 mM K). Note prolongation of Ca inward current after K-depletion in (*a*,) and depression of current after washing in (*b*). Similar changes are observable in the tail currents. *c*, Voltage–current relationships before and after K-depletion. Long depolarising pulses (1.0 s) were used. ○, □, Control. ●, ■, 10 min after K-lack *d*, As (*c*), but in Na-free sucrose Ringer solution. ○, □, Control. ●——■, 3 min after K-lack. ● . . . ■, 10 min after K-lack. In (*c*), both inward and outward terminal currents (squares) were markedly inhibited while fast dynamic inward currents (○) were unaltered. In (*d*), no anomalous rectification was observable due to Na-free condition. Note apparent enhancement of I_{Ca} (○) at 3 min after K-depletion.

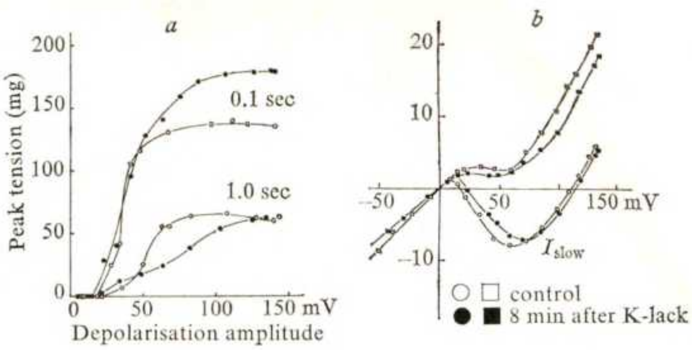

Fig. 3 Late effects of K-depletion on membrane currents and tension components under voltage clamp. *a*, Voltage-tension relationships. Short and long depolarising pulses (0.1 s and 1.0 s) were used and peak tension before (○), and 10–15 min after (●) K-depletion were plotted against amplitude of pulses. The contractile tensions in response to short pulse (mainly I_{Ca}-dependent tension) were inhibited while those for long and strong pulses (largely I_{Ca} -independent tension) were augmented. *b*, Voltage–current relationships before (○, □) and 8–10 min after (●, ■) K-depletion in presence of tetrodotoxin (5×10^{-7} g ml^{-1}). The squares mark terminal currents and the circles, peak inward currents. Long pulses (1.0 s) were used. The slow inward current and the inward as well as outward terminal currents were depressed.

It should be noted that these initial and late effects of K-depletion seemed to be quite similar to those of ouabain[12,13]. Although the mechanism of therapeutic action of ouabain is not yet known, one possibility suggested by Baker *et al.*[14] and Langer[15] is that inhibition of the Na pump and the consequent increase of $[Na]_i$ may allow an accumulation of Ca into the cell through the Na–Ca exchange mechanism. In fact, ouabain was shown by Vassort[16] to increase only the I_{Ca}-independent tonic tension in frog atrium, which largely depends on Na–Ca exchange. This may be compatible with the late inotropic effect of K-depletion in our case where the Na pump was also inhibited[8]. Another possibility has been proposed[17,18], however—a therapeutic low dose of ouabain may produce net stimulation rather than inhibition of the Na/K-ATPase. Blood[19] used doses of ouabain (5×10^{-10} to 10^{-7} M) that exert a definite positive inotropic action on Purkinje fibre. These doses were found by Cohen *et al.*[20] to increase the K gradient across the membrane, probably as a consequence of stimulation of the Na pump. These effects may well correspond to the initial effects of K-depletion, at least in the condition in which $[K]_0$ decreases. The inotropic action of cardiac glycosides is probably not mediated by an increase of I_{Ca}, but rather, is accompanied by its decrease[12,13]; however, the effects of a low dose on I_{Ca} have not been examined. In any case, the appearance of I_{Ca} augmentation after K-depletion may explain some part of the long known antagonistic action of Ca and K on myocardial contractility.

Sarcomere shortening in striated muscle occurs in stepwise fashion

During the development of a high resolution light diffractometer to study sarcomere dynamics, we have observed an unexpected feature of the pattern of sarcomere shortening. We report here that sarcomere shortening during contraction seems to occur in a series of successive bursts punctuated by short but well defined periods during which motion has virtually ceased. Furthermore, it seems that this stepwise pattern of shortening may occur synchronously over many contiguous sarcomeres.

Cardiac and skeletal muscle specimens were mounted in an apparatus (Fig. 1), components of which have been described[1]. The muscle was transilluminated with laser light (Spectra Physics He-Ne laser, Model 120, $\lambda = 0.6238\ \mu$m). The diffraction pattern was collected at the rear focal plane of a water immersion objective (Zeiss ×40, effective numerical aperture 0.5). Sarcomere length was computed from the spacing between diffracted orders using the Fourier relationship.

We use three methods of analysis (Fig. 1). With each method the diffraction pattern was first compressed along the length of each order with a cylindrical lens; this increased intensity and averaged optical noise. The compressed pattern was then projected on the three sensors. The principal sensor was a 128-element photodiode array (Reticon RL-128A; diode spacing 50 μm; aperture 25 μm × 430 μm). The array was scanned 5 times per ms. Each scan generates a profile of intensity against spatial frequency of the striation pattern. Sarcomere length was computed during each scan from the distance between the zeroth order peak and the computed median of the first order (T.I. and G.H.P. in preparation). The sarcomere length signal was calibrated with a series of gratings; the accuracy was within 1% between 1.6 μm and 3.3 μm. Resolution was approximately 5 nm.

In the second method a slice of the diffraction pattern was projected through a slit (width 0.9 mm) on to film in a kymographic camera[2]. The time resolution was limited to about 4 ms. Densitometry measurements were made at intervals of 2 ms along the film, and a plot of intensity against spatial frequency was obtained at each location. The position of the median of the first order was determined by planimetric integration. Sarcomere length was computed from the spacing between the median and the zeroth order peak. From these computations a plot of sarcomere length against time was obtained.

Fig. 1 Apparatus used to measure sarcomere length with high time and length resolution. The diffraction pattern of the muscle collected at the rear focal plane of the objective lens is projected onto three sensors for analysis. Sarcomere length is derived from the spacing between bands of the diffraction pattern.

In the third method, one of the first orders was projected through a slit onto a Schottky barrier photodiode (United Detector Tech. SC/25). The photodiode has a cathode at each end, and the difference of cathode currents is directly related to the position of the centroid of the light spot. Sarcomere length was computed from this current difference, giving a continuous output with a bandwidth of about 100 kHz. Calibration error was within 3% throughout the relevant range of striation spacings.

Representative examples of the time course of sarcomere shortening during contraction obtained with the photodiode array are shown in Fig. 2. These are records of 'internal' shortening during isometric twitches (though comparable phenomena were observed in non-isometric twitches and

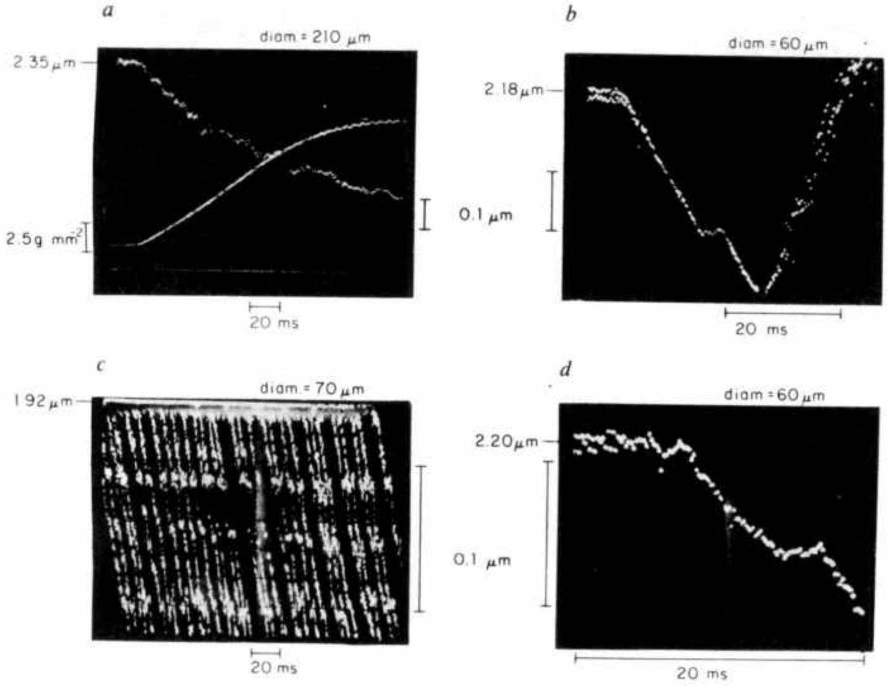

Fig. 2 Records of the time course of sarcomere length during contraction, taken from rat papillary (*a*), frog skeletal (*b* and *d*) and rat trabecular (*c*) muscle. All records were obtained using the photodiode array. In (*a*) the tension record and the stimulus pulse are shown as well. Note the stepwise shortening pattern observed early in the contraction. In the twitch depicted in (*b*) only one step is seen, lasting about 4 ms. The trace becomes noisy during relaxation as a consequence of the breakup of the diffraction pattern, as reported previously[2]. The Records in (*c*) are from a series of contractions (each displaced successively rightward) and demonstrate the repeatability of the stepwise pattern. Because of the expansion of the sarcomere length scale relative to the time scale, each plateau appears as a bright spot on the trace. Record (*d*) was obtained with high time and sarcomere length sensitivity on the oscilloscope, so that each sarcomere length determination showed up distinctly. Only the early portion of contraction is shown. The transition between shortening and plateau (right side of panel) occurs within several hundred microseconds, the time for one or two sarcomere length determinations.

tetani). In Fig. 2*a* shortening commenced after a latent period following stimulation and continued for several milliseconds. Then, abruptly, shortening ceased and did not resume for 8–10 ms (a period encompassing 40–50 determinations of sarcomere length). This stepwise shortening pattern was repeated several times during the early phase of contraction. Later in the cycle the signal became irregular and failed to show distinct plateaus. Thinner specimens often showed plateaus throughout the shortening phase of contraction, possibly because of their relatively sharper diffraction patterns.

Figure 2*b* shows a shortening pattern obtained from a single fibre of skeletal muscle. Only one distinct plateau is evident. Although other records did show multiple plateaus, we usually found fewer and shorter plateaus than in comparable contractions of cardiac muscle. The series of shortening traces in Fig. 2*c* was obtained from successive contractions in the same optical region of a trabecular specimen. As this record shows, plateaus occurred at approximately the same sarcomere length in every contraction. In different regions along the specimen, however, different stepwise shortening patterns were usually found, and in some regions no steps were evident.

Figure 2*d* shows a portion of a shortening trace recorded with high sensitivity to illustrate the abruptness of the transition between shortening and plateau. Transitions were usually complete within 1 ms.

Stepwise shortening patterns might arise artefactually from at least two potential sources. The specimen could translate across the optical field from a shortening to a static region. We have seen such patterns, however, in regions which translated only several per cent of the field diameter throughout contraction. Another potential source of artefact is the photodiode array and associated electronics. To test this, we recorded some diffraction patterns simultaneously using both the photodiode array and the kymographic technique outlined in Fig. 1.

Analysis of the kymographic records was not entirely satisfactory, as the limited time resolution precluded the delineation of any sharp corners in the shortening pattern. Furthermore, faithful representation of the shortening pattern placed high demands on the accuracy of the planimetric determinations; relatively minor errors produce enough scatter to blur fine details of the shortening pattern.

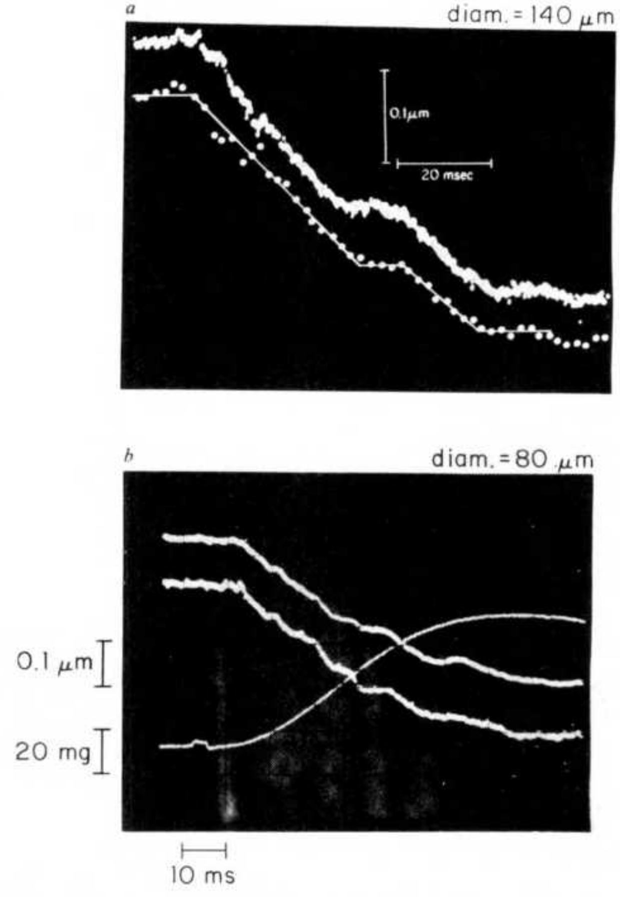

Fig. 3 Time course sarcomere length (from rat trabecular muscle) measured simultaneously with the photodiode array (continuous curve) and with the kymographic technique (points). The records are vertically displaced for clarity. Initial sarcomere length was 2.3 μm. A plateau seems to be present in both records at a point just beneath the sarcomere length scale; however, the restricted time and space resolution of the kymographic technique limits the confidence with which the existence of a plateau can be inferred. *b*, Time course of sarcomere length changes measured simultaneously with the photodiode array (upper trace) and the Schottky barrier photodiode (middle trace). Records are vertically displaced for clarity. Initial sarcomere length was 2.1 μm. The tension record, with superimposed stimulus artefact, is shown beneath.

Nonetheless, these records showed a fair degree of correspondence with those obtained with the photodiode array (Fig. 3*a*).

Because we judged the correspondence between the two results to be inconclusive, we adopted still another methodology, the Schottky barrier photodiode (Fig. 1). As Fig. 3*b* shows, the records obtained with this analogue technique show a stepwise shortening pattern similar to that obtained simultaneously with the photodiode array. The similarity of the records convinces us that the spacing between the zeroth and first order changes in stepwise fashion.

If so, the shortening behaviour among a large fraction of the sarcomeres in the optical field must have been coordinated; otherwise the sharp corners in the shortening trace could not have been observed. Since each field covered approximately 180 μm, the region of spatial coherence must have extended over at least the major fraction of this dimension. On the other hand, we found regional variations along the muscle of the step-like shortening patterns, so that the region of spatial coherence apparently did not extend far beyond the dimension of an optical field.

Plateaus in the shortening patterns could arise in at least three ways: (1) most sarcomeres in an optical field could undergo no length change during the period of the plateau; (2) populations of lengthening and shortening sarcomeres could cancel one another, or (3) all sarcomeres might shorten continually, but the contribution to the diffraction pattern of the shorter sarcomeres could diminish gradually (due perhaps to increasing misregistration of sarcomeres), as the contribution of the longer sarcomeres gradually increases.

Possibility (3) requires that at least two distinct sarcomere populations exist within the optical field, that the degree of spatial coherence of each be cyclic and out of phase with the other, and that the cycles occur at specific sarcomere lengths. The combination of these *ad hoc* assumptions seems too unrealistic to make this explanation likely. Possibility (2) demands that a fraction of sarcomeres in the field suddenly begins lengthening just rapidly enough to cancel the contribution of shortening sarcomeres. By the end of a plateau the two populations ought to have diverged by an amount detectable on the kymographic records; we observed no such divergence. Thus the first possibility—that most sarcomeres in the field suddenly cease shortening—remains the most likely explanation of the plateaus in the stepwise shortening pattern.

If our observations withstand the test of time, any proposed molecular theory of contraction would have to incorporate a mechanism to account both for stepwise shortening in a single contractile unit, and for synchronisation of this stepwise pattern among a large number of contiguous contractile units. It is not immediately obvious how the cross-bridge theory as now envisaged[3,4] might satisfy such a requirement.

Does electrophoresis of cockroach muscle proteins detect recognition molecules?

IN some animals, particularly amphibia and insects, normal function is ultimately restored in a limb which has been denervated. In the cockroach it has been shown that identified motoneurones reinnervate the same leg muscles as they did before the nerve was sectioned[1,2]. A possible explanation is that each muscle has specific molecules by which ingrowing nerves are able to recognise their appropriate destination. Recently, Denburg[3], using sodium dodecyl sulphate (SDS)–polyacrylamide gel electrophoresis has shown that these cockroach muscles have distinct gel protein patterns which he suggests represent specific recognition molecules. Alternatively, the differences may arise because the motor neurones he considers are physiologically different types, 'fast' and 'slow'. To test this interpretation we have examined a number of other cockroach muscles using Denburg's methods. All the muscles have patterns which may be grouped into the same categories as Denburg's even though they are innervated by different neurones. Where the innervation by 'fast' and 'slow' neurones is known the correspondence with our data is good. Furthermore, locust flight muscles with solely 'fast' innervation all have identical patterns. We conclude that gel electrophoresis patterns demonstrate a characteristic of the type of innervation rather than representing specific recognition molecules.

On theoretical grounds it seems unlikely that a procedure as crude as SDS gel electrophoretic analysis of whole muscle extract should reveal molecules concerned in specific recognition by motoneurones. One might reasonably expect that every

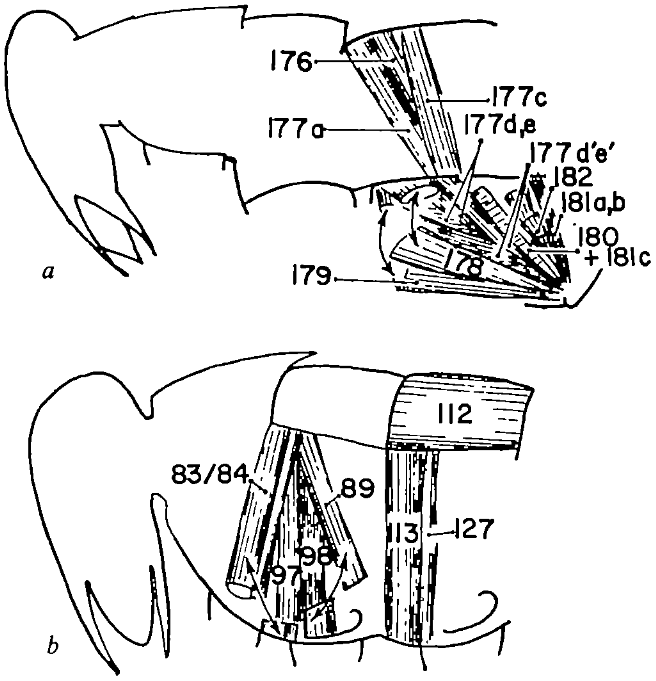

Fig. 1 *a*, Positions of the muscles in the cockroach which have been examined by SDS–polyacrylamide electrophoresis (see Fig. 2). The muscles are numbered according to Carbonell[5]. Muscles 161, 163 and 167 lie close to 177a and have been omitted for clarity. Muscle 174 lies close to 176 and is omitted also. *b*, Positions of the flight muscles in the locust which have been examined (see Fig. 3).

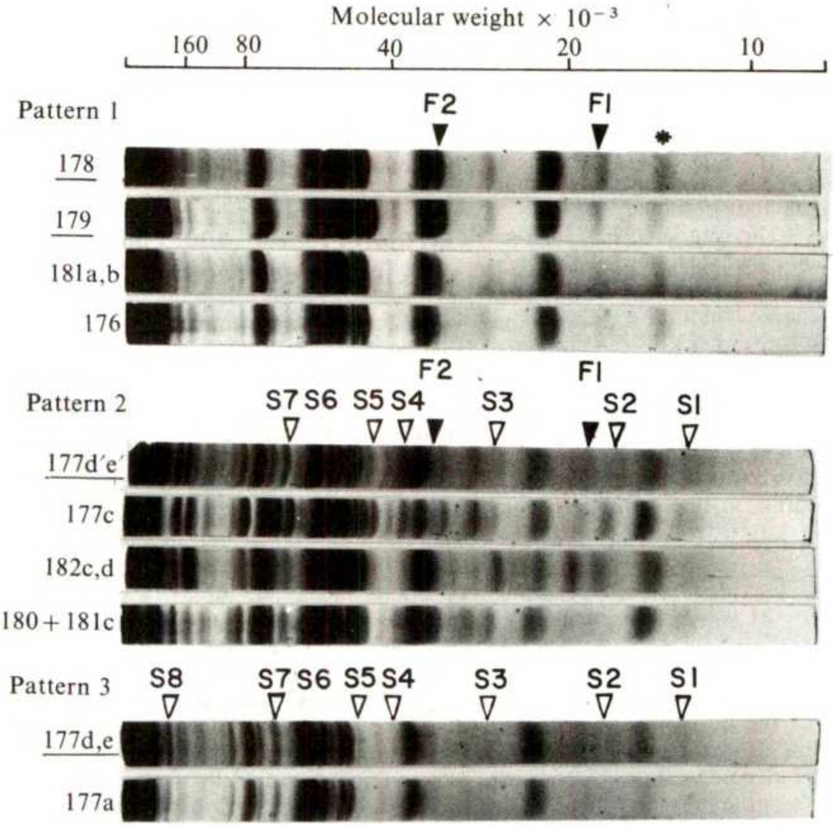

Fig. 2 SDS–polyacrylamide gels of the cockroach muscles shown in Fig. 1*a*, stained with Coomassie Blue. The numbers of the muscles examined by Denburg are underlined and those bands corresponding to the R_f values of his bands F1–2 and S1–8 are indicated. An additional band (labelled *) not described by Denburg is also indicated. This figure demonstrates that the patterns 1–3 from the muscles Denburg examined are not unique to muscles innervated by motoneurones 28 and 52, which argues strongly against their representing specific recognition molecules. Isolated muscles were homogenised in an appropriate volume of 0.01 M Tris-HCl (*p*H 7.4), 20% gylcerol, 1% SDS and 5% 2-mercaptoethanol and heated in a boiling water bath for 5 min. Aliquots of these solutions were applied to 10% polyacrylamide gels which were run in the presence of 0.2% SDS, stained with Coomassie Blue, and destained using the methods of Fairbanks *et al.*[4]. The gels have been severed at the dye marker band.

structural and soluble protein of the cell would be represented in the extract and yet the largest number of bands we have observed using Denburg's technique is 33. Clearly only those proteins with the largest representation in the cell are being made visible by the method and it would seem improbable that specific recognition molecules, which have previously evaded identification would be in the top 33.

Denburg found that the metathoracic coxal depressor muscles 178 and 179, which are innervated by cell 28, have a banding pattern different from that of muscles 177d and 177e which are innervated by cell 52. The gel patterns for muscles 177d′ and 177e′, which are innervated by both motoneurones, have features common to both types (Figs 1*a* and 2). He considers that particular bands in these patterns represent distinctive macromolecules by which ingrowing nerves are able to recognise their appropriate muscle. Our alternative explanation is that the gel protein pattern for muscles innervated by cell 28 is different from those of muscles innervated by cell 52 simply because cell 28 is a 'fast' motoneurone, while cell 52 is a 'slow' motoneurone. If this interpretation is correct then all muscles with 'fast' innervation should show the one pattern, those with 'slow' the other, and muscles innervated by both kinds of neurone should show the sum of the two patterns. Unfortunately Denburg only analysed the muscles which are innervated by cells 28 and 52 and he did not test this possibility.

We have examined 14 cockroach muscles using the same method of SDS–polyacrylamide gel electrophoresis[3,4] and have obtained banding patterns very similar to his for the muscles he analysed (Fig. 2). Muscles 178 and 179 have a pattern which includes the bands which Denburg labels F1 and F2 (Fig. 2, pattern 1). Muscles 177d′ and 177e′ have a pattern with the F1 and F2 bands and also the bands S1–7 (Fig. 2, pattern 2). The pattern from muscles 177d and 177e does not have the F1 and F2 bands but has bands S1–7 and an additional band, S8, which is supposed to be associated with inhibitory innervation[3] (Fig. 2, pattern 3). Our gels show a number of differences from

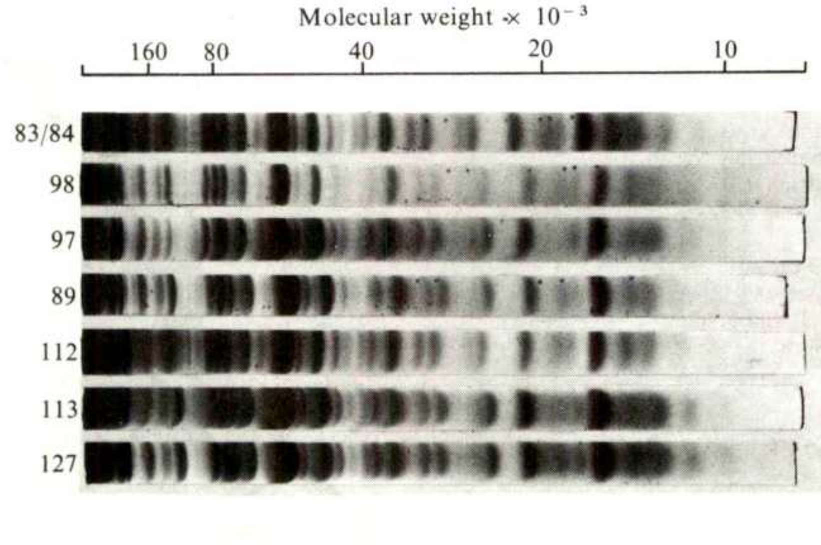

Fig. 3 SDS gels of the locust muscles shown in Fig. 1*b*, prepared in the same way as those in Fig. 2. The cells innervating these muscles are known[10-12] and are distinct, and yet the banding patterns show no distinct differences from one another. It is concluded that none of these bands can represent molecules by which ingrowing nerves could recognise specific muscles.

Denburg's, for example, an additional band labelled * (Fig. 2) but these are minor.

Analysis of other cockroach muscles (Fig. 1) shows that coxal muscles 181a, b and 182, and the thoracic muscles 174 and 176 also show pattern 1 (Fig. 2). Muscles 180 and 181c, 182c, d and 177c show pattern 2, which is also seen in the thoracic muscles 161, 163 and 167 (not illustrated). Muscle 177a shows the pattern 3 banding (Fig. 2). These results show that the characteristic patterns are not confined to those muscles innervated by cells 28 and 52 and argues against their representing specific recognition molecules. Intracellular microelectrode recording from the metathoracic coxal muscles[6,7] and from the homologous muscles in the mesothoracic segment[8] tends to support the alternative hypothesis that the patterns are related to 'fast' and 'slow' innervation (see Table 1). Pattern 1 muscles 181a, b are the homologues of the mesothoracic muscles 139a, b which Usherwood[8] has shown have only 'fast' innervation. The innervation of 174 and 176 is unknown but it is predicted that these have only 'fast' innervation. Pattern 2 muscles 182c, d have 'mixed' innervation[7], while 180 and 181c are homologous with 138 and 139c which also have 'mixed' innervation[8]. The innervation of thoracic muscles 161, 163 and 167 is unknown but it is predicted that these also have 'mixed' innervation. There are two anomalous results. Muscle 177a is a pattern 3 muscle and 177c is a pattern 2 muscle yet the mesothoracic homologues 135a and 135c have only 'fast' innervation[8]. This may reflect a true difference between the meso- and metathoracic segments, but it is more likely that the discrepancy arises from the difficulty of identifying unequivocally the subdivisions of these muscles from the accounts given in the literature[5,9].

Further evidence against Denburg's interpretation is provided by analysis of a group of flight muscles in the locust (Fig. 1*b*) in which the innervation is well known both physiologically and by intracellular filling of the motoneurones[10-12]. Muscles 97, 113 and 127 each have one 'fast' motoneurone, muscles 83/84, 89 and 98 are innervated by the two 'fast' neurones each, and 112 by five 'fast' neurones[10-12]. The banding patterns from extracts of these muscles are different from those in the cockroach, but almost identical with each other (Fig. 3). Each of these muscles has a distinct role in flight behaviour, and coordination would be impossible if a muscle were wrongly innervated. Even so, depressor muscles 97 and 127 which are immediately adjacent to elevator muscles 83/84 and 113 (Fig. 1*b*) have the same banding pattern. The bands detected by electrophoresis cannot, therefore, represent molecules by which an ingrowing nerve recognises its correct muscle. It is concluded that the bands observed are characteristic of 'fast' innervated locust muscle.

Table 1 Summary of analysis of cockroach muscles (column 1), and their pattern types as determined by polyacrylamide gel electrophoresis (column 3)

Metathoracic muscle number	Equivalent mesothoracic muscle number (where relevant)	Pattern type	Type of innervation
178	—	1	Fast[6]
179	—	1	Fast[6]
181a, b	139a, b	1	Fast[8]
174	—	1	Unknown
176	—	1	Unknown
177d′, e′	—	2	Mixed[6]
180+181c	138+139c	2	Mixed[8]
182c, d	—	2	Mixed[7]
161	—	2	Unknown
163	—	2	Unknown
167	—	2	Unknown
177c*	135c	2	Fast[8]*
177d, e	—	3	Slow
177a*	135a	3	Fast[8]*

The equivalent muscles in the mesothoracic segment for which the innervation is known from microelectrode studies[8] are given in column 2. The type of innervation deduced from these and other microelectrode studies[6,7] is given in column 4. The two anomalous results are shown by *. These may be caused by difficulty of identifying unequivocally these subdivisions of muscle 177.

We suggest that the distinctive bands detected by gel electrophoresis of whole muscle are indicative of the physiological type of the muscle rather than representing specific recognition molecules. They could be associated with either the receptor proteins or contractile mechanisms and this is worth investigating further. An immediate benefit of the results is that they demonstrate that the method may be useful for identifying the type of innervation of individual muscles.

We thank Dr Denburg for stimulating correspondence over our differences in interpretation of these results and for pointing out a discrepancy in our original interpretation of the gels for muscle 182c, d. We thank also Dr K. J. Indge and Mr G. Perry for help with electrophoresis and Drs J. S. Altman and M. D. Houslay for reading the manuscript.

Increased membrane fluidity precedes fusion of muscle cells

Embryonic skeletal muscle cell cultures are highly suitable for demonstrating the dynamic role of the plasma membrane in cellular differentiation. A primary event in the overt development of muscle in culture is fusion of the plasma membranes of neighbouring mononucleated myoblasts to form multinucleated myotubes[1,2]. Previous studies of muscle fusion have focused on ultrastructural[3] and electrophysiological[4] aspects, the requirement for Ca^{2+} (ref. 5), and the importance of fusion for the subsequent biosynthesis of muscle-specific proteins[4]. But, understanding of this process has been hampered by the absence of reliable markers for the initiation of myoblast fusion[4]. In addition, the importance of the lipid properties of the cell membrane in regulation of the onset of muscle fusion has not been unambiguously demonstrated in spite of the well-established role of lipids in other cases of membrane fusion[6]. We examined the possibility that fusion of myoblasts is regulated by changes in the lipid fluidity of the cell membrane, as measured by the rotational diffusion of a fluorescent probe. We report here that, as a primary step in myogenesis in culture, mononucleated myoblasts undergo a sharp decrease in membrane microviscosity, and shortly afterwards fuse rapidly to form multinucleated myotubes. The microviscosity remains at a minimal value during the period of rapid cell fusion. The subsequent post-fusional differentiation of the muscle cell is accompanied by the regeneration of membrane rigidity.

Primary cultures of embryonic chick breast muscle cells were prepared[7] and plated at initial densities of $1.5–2 \times 10^6$ cells per 60-mm culture dish. Cultures were grown in Dulbecco's modified Eagle's medium[8] (88%, v/v) supplemented with horse serum (Gibco, 10%, v/v) and chick embryo extract (2%, v/v). The extent of fusion was expressed as the fraction of nuclei located in multinucleated cells[9].

Microviscosity was determined by monitoring the fluorescence polarisation of the lipid probe 1,6-diphenyl-1,3,5-hexatriene (DPH) as previously described[10,11]. Fluorescence labelling of cultured muscle was carried out by incubating muscle cell suspensions in Dulbecco's phosphate-buffered saline (PBS) (ref. 12) containing 1 μM DPH (ref. 11) for 15 min at 37 °C. Labelled cells were washed and suspended in PBS at a concentration of 0.2–0.4 mg cell protein per ml. As shown by fluorescence microscopy, the DPH-induced fluorescence was confined to the muscle cell periphery.

In the culture conditions used in this study, the differentiation of muscle cells is marked by a high degree of synchrony. Within an interval of approximately 1 d, synchronously differentiating cultures of embryonic chick myoblasts withdraw from the mitotic cycle, undergo rapid fusion, and initiate the accumulation of contractile proteins[9] and specialised membrane components such as the acetylcholine receptor and acetylcholinesterase[13]. As shown in Fig. 1, fusion of myoblasts was initiated during the second day in culture. The proportion of fused cells increased sharply and most nuclei were located in multinucleated myotubes within several hours. During the initial day in culture and before fusion, myoblasts underwent a steep decrease in microviscosity (Fig. 1). The microviscosity reached minimal levels concomitantly with onset of myoblast fusion and remained unchanged during the main period of fusion. Shortly after the degree of fusion had reached a maximum, an increment in microviscosity could be detected. Post-fusional differentiation of myotubes was accompanied by a continuous increase in microviscosity (see Fig. 1) coinciding with the developmental changes in biochemical[13] and electrophysiological[14] properties of the muscle cell membrane. This rise was maintained during the second week of maturation in culture to reach values higher than the initial microviscosity measured at the time of plating. Thus the pre-fusional decrease in microviscosity is a transitory event which is reversed in the course of subsequent differentiation of muscle in culture.

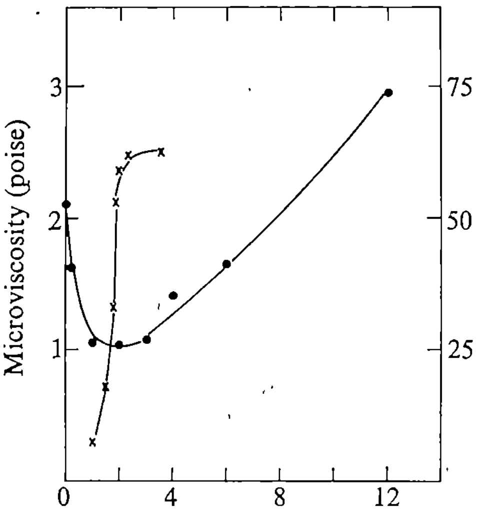

Fig. 1 Kinetics of fusion and change in microviscosity during differentiation of embryonic chick skeletal muscle in culture. Fusion (×) is expressed as the % of nuclei found in multinucleated cells. Microviscosity (●) was measured at 25 °C as before[10,11] with muscle cells labelled with DPH as follows. Cultures were rinsed with PBS and cells were suspended by 5 min exposure to 0.2% trypsin solution (Gibco). After a rinse with 5 ml PBS containing 0.25 mg Lima bean trypsin inhibitor (Sigma), the cells were resuspended in the labelling dispersion of 1 μM DPH in PBS and incubated at 37 °C for 15 min. The cells were collected by centrifugation at 2,000 r.p.m. for 5 min and resuspended in PBS. As an alternative procedure, the muscle cell monolayer was fluorescently labelled on the culture dish by exposure to 5 ml of the labelling dispersion for 15 min at 37 °C. The cells were rinsed with buffer, removed from the dishes as described above, rinsed and resuspended in PBS. Similar results were obtained with both labelling procedures. For convenience, cells were routinely labelled in suspension and measurements were performed with 0.2–0.4 mg cell protein per ml PBS.

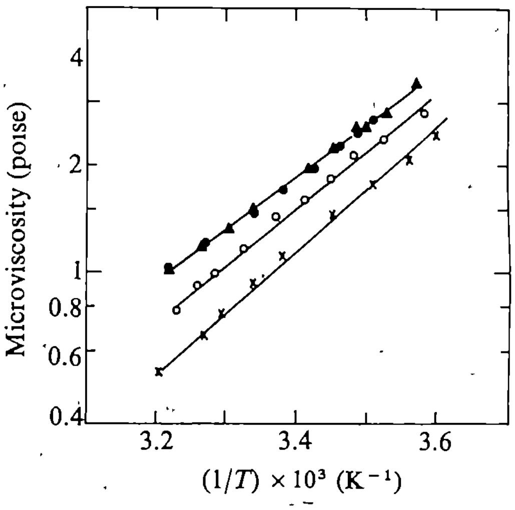

Fig. 2 Temperature dependence of microviscosity of muscle cultures at various stages of development; ●, 5 h; ×, 48 h; ○, 96 h; ▲, 144 h after plating.

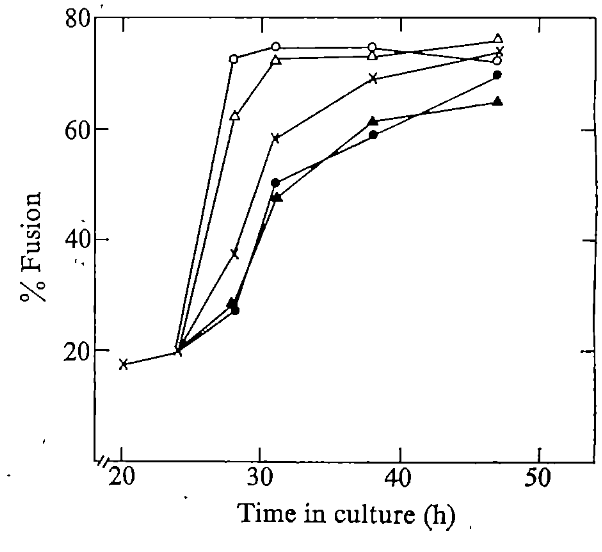
Figure 2 shows the dependence on temperature of microviscosity in muscle cells at various stages of maturation. As shown, the relation between microviscosity (η) and the absolute temperature (T) fits the expression $\eta = A\,\exp(\Delta E/RT)$ which eliminates the possibility of lipid phase transitions in the muscle cell membrane both before and after fusion[15]. As calculated from the plots of log η against $1/T$ (Fig. 2), the flow activation energy (ΔE) for all cultures tested, falls in the range of 6.5–8.0 kcal mol^{-1}, a value characteristic of cell membranes[11].

The marked increase in membrane fluidity observed before the fusion of myoblasts is consistent with the suggestion that high lipid fluidity is essential for fusion[16].

Fig. 3 Effects on kinetics of fusion of exposure of myoblasts to fatty acids. Fusion was scored after addition of 2×10^{-5} M stearic (●), elaidic (▲), oleic (△) or linoleic (○) acids to replicate culture dishes 24 h after plating and compared with control cultures (×). The extent of fusion was expressed as the fraction of nuclei located in multinucleated cells[9].



This notion is supported by the reported inhibitory effects of cholesterol and reduced temperature on myoblast fusion[17]. Moreover, we have observed that exposure of myoblasts to fatty acids that increase membrane microviscosity (stearic or elaidic acids, 2×10^{-5} M) (ref. 18) retarded fusion (Fig. 3). Conversely, treatment of cells with fatty acids that decrease membrane microviscosity (oleic or linoleic acids, 2×10^{-5} M) (ref. 18) facilitated fusion. These findings suggest the importance of cell membrane lipid properties in the regulation of muscle cell fusion and indicate that the sharp increase observed in myoblast membrane fluidity is a reliable marker for the initiation of fusion. The transient fluidisation of the myoblast membrane which allows fusion could be regulated by developmental changes in lipid composition such as an overall increase in phospholipid content or increase in the degree of unsaturation of acyl chains.

Evidence for multispecificity of antibody molecules

ONE of the salient questions in immunology concerns the means by which the immune system is capable of recognising an apparently limitless variety of antigenic determinants, including many that presumably did not exist during its evolution. Three major hypotheses have been put forward to explain the diversity of the immune response: a stringent germ line hypothesis, a recombinational germ line hypothesis and a somatic mutation hypothesis (see ref. 1 for discussion). If the assumption is made that an antibody-combining site has a single antigenic specificity, the first of the above hypotheses postulates about 1,000 variable genes and 1,000 constant genes to code for about 10^6 antigenic determinants. The second and, especially, the third hypotheses require the presence of many fewer genes in the germ line. Even fewer genes would be required if antibody-combining sites were multispecific. Evidence has been put forward to support the concept of multispecificity[2]. Moreover, the ability of single myeloma globulins to bind structurally diverse molecules[3] and the multispecific character of a Bence-Jones[4] dimer can be taken as additional supportive evidence. In an earlier paper[5], we attempted to investigate the question of multispecificity by studying the binding specificities of a population of antibodies of limited heterogeneity generated by immunisation with a conjugate of adenosine-5′-phosphate and gramicidin S: $(AMP)_2$–gramicidin S (ref. 6). Immunised rabbits produced predominantly three or four globulin proteins specific for AMP. Binding studies on the sera of one of the rabbits, in which there were three major AMP-specific globulins, yielded data that could be interpreted as evidence for multispecificity of antibody-combining sites. We have now succeeded in isolating three homogeneous anti-AMP antibodies from one of the rabbits immunised with $(AMP)_2$–gramicidin S and have studied the ability of each globulin to bind AMP and other ligands. The isoelectric pattern of the specifically purified[7] population of antibodies obtained from the serum of rabbit 449 (ref. 5) showed three major bands. The three bands were separated and isolated by preparative isoelectric focusing in polyacrylamide by an adaption of the procedure of Wrigley[8], and were shown to be homogeneous by analytical isoelectric focusing. They were designated fractions A, B and C.

Table 1 Inhibition of reaction between antibody and AdGase by haptens (relative concentration for 50% inhibition)*

Inhibitors	Fraction A	Fraction B	Fraction C
AMP	1 (8 nmol)†	1 (8 nmol)	1 (10 nmol)
DNP–glycine	75	8	100
DNP–lysine	75	10	>1,000
Menadione	2	16	>1,000
Hydralazine	825	26	>1,000
Caffeine	6	50	4
GMP	575	83	>1,000
Sodium barbital	>1,000	>1,000	>1,000
Procaineamide–HCl	>1,000	>1,000	>1,000
CMP	>1,000	>1,000	>1,000
UMP	>1,000	>1,000	>1,000
TMP	>1,000	>1,000	>1,000

*Twenty-five microlitres of a 1:50 dilution of each purified antibody (final concentration about 5 μg ml^{-1}) in 0.85% NaCl–1% rabbit serum albumin were incubated with 25 μl inhibitor (1 nmol to 10 μmol) in 0.85% NaCl for 2 h at 25 °C. To this mixture was added 25 μl Ad Gase (ref. 9) (originally 10 mg ml^{-1}) diluted 1:10,000 in 0.1 M phosphate buffer, *p*H 7.0. After incubation at 4 °C overnight, 25 μl normal rabbit globulin (2 mg ml^{-1}) and 200 μl of sheep antirabbit globulin (25 mg ml^{-1}) were added and the mixture was incubated for another 2 h at 4 °C. Seven-tenths of a milliliter of 0.01 M Tris-HCl buffer, *p*H 7.5, containing 1% RSA, 0.01 M $MgCl_2$, 0.01 M NaCl and 0.01 M mercaptoethanol were added to each tube. The tubes were then centrifuged at 3,700*g* for 15 min at room temperature. One-hundred microlitres of the supernatant were added to a test tube containing the following mixture: 1.0 ml 0.3 M phosphate buffer, *p*H 7.0, containing 0.003 M $MgCl_2$, 0.6 ml distilled water, 0.3 ml 1 M mercaptoethanol and 1.0 ml solution of fluorogenic substrate, 4-methylumbelliferyl-β-D-galactopyranoside (Nortok Associates, Lexington, Massachusetts) taken from a solution containing 14 mg per 100 ml in 0.3 M phosphate buffer, *p*H 7.0. The mixture was incubated at 25 °C for 18 h. Then, 2 ml 0.5 M glycine–NaOH buffer, *p*H 10, were added to the assay mixture to terminate the reaction, and the fluorescence was measured in a Perkin Elmer Model MPF-2A Fluorescence Spectrophotometer (excitation 360 nm, emission 440 nm). Normal rabbit globulin (1:50 dilution) was used in place of antibody as a control.

†Figures in parenthesis indicate amount of AMP to give 50% inhibition.

The specificity of each antibody was examined by an enzyme immunoassay procedure, in which binding of adenosine-β-galactosidase[9] (AdGase) was determined in the presence and absence of competing ligands. The results are given in Table 1. For all three fractions, AMP inhibited binding of Ad Gase best, but CMP, UMP, TMP and, except for fraction B, GMP were relatively poor inhibitors. On the other hand, fraction A cross reacted significantly with menadione, caffeine, DNP–glycine and DNP–lysine. Fraction B was the least discriminating of the antibodies, significant cross reactions being observed with six ligands. Fraction C, on the other hand, cross reacted well with only one of the ligands chosen for our studies, namely caffeine.

The results given in Table 1 were confirmed for fraction A by a haemolytic assay with sheep red blood cells coated with adenosine (Table 2). Inhibition of haemolysis was best with AMP followed in order of decreasing effectiveness by menadione, caffeine and DNP–glycine. GMP, hydralazine, sodium barbital and procaineamide were very poor inhibitors. These results closely approximate those obtained in the enzymeimmunoassay (Table 1).

To estblish with greater certainty that cross reactions were indeed occurring at the combining sites of the antibodies, a study was made of direct binding of ligand-coated red cells and subsequent lysis by complement. The results (Table 3) show that fractions A and B caused lysis of AMP-, DNP- and menadione-coated cells. Fraction C did not cause lysis of menadione-coated cells. These results are consistent with the findings presented in Tables 1 and 2.

Table 2 Haemolytic inhibition assays with fraction A and sheep erythrocytes coated with adenosine*

Inhibitors	Inhibition Titre†
AMP	1 nmol
Menadione	1 nmol
Caffeine	5 nmol
DNP–glycine	50 nmol
GMP	100 nmol
Hydralazine	100 nmol
Sodium barbital	100 nmol
Procaineamide–HCl	1 μmol

*Adenosine-coated erythrocytes were prepared as follows. Adenosine (20 mg) was dissolved in 1 ml 0.1 M $NaIO_4$ and allowed to stand for 20 min in the dark. One drop of ethylene glycol was then added. A 5% sheep erythrocyte suspension (1 ml) in 0.01 M phosphate-0.85% NaCl, *p*H 7.5 (PBS), was added to the periodate solution and the *p*H was adjusted to 8 with 0.1 M NaOH. Thirty minutes later, 83 mg $Na(H_3BCN)$, freshly dissolved in 1.0 ml PBS was added and the suspension was allowed to stand for another 15 min. The adenosine-coated erythrocytes were then washed twice in PBS and made up as a 0.75% (v/v) suspension in PBS. The passive haemolytic titre of fraction A was determined by microtitration; PBS, *p*H 7.0, was used as diluent. Aliquots (25 μl) of serially twofold-diluted antibody samples, 25 μl 0.75% (v/v) suspension of adenosine-coated sheep erythrocytes, 5 μl sheep anti-rabbit globulin (diluted 1:100) and 10 μl guinea pig complement (Pel-Freez Biologicals) (diluted 1:10 with PBS) were pipetted, in that sequence, into test tubes. After 1 h at 37 °C, the haemolytic endpoint was found to be at 1:16 dilution of antibody. For the haemolytic inhibition studies, 5 μl various inhibitors (100 pmol to 1 μmol) were added to 25 μl fraction A diluted 1:8. After 1 h at room temperature, 25 μl 0.75% adenosine-coated erythrocyte suspension, 5 μl sheep anti-rabbit globulin (diluted 1:100 in PBS) and 10 μl guinea pig complement (diluted 1:10 in PBS) were added. Haemolysis was allowed to proceed for 1 h at 37 °C and the titre determined.

†Lowest quantity of inhibitor for which there is still inhibition of haemolysis.

Cross specificity could also be demonstrated at the surface of lymphocytes. Peripheral lymphocytes were obtained[10] from rabbit 449. Their ability to bind AdGase in the presence of various ligands was determined by a modification of a published fluorometric assay[9,10]. The results (Table 4) show that at the single concentration measured, AMP, menadione and hydralazine were essentially identical in their ability to displace AdGase from the population of lymphocytes capable of binding the latter. With respect to the other ligands, the activities were as follows: barbital > caffeine > GMP > DNP–glycine. Procaineamide and UMP were essentially inactive. The results show that receptor sites on peripheral lymphocytes are also multispecific. Generally, ligands that competed well were the same ones that did so in the experiments with circulating antibody. Exact comparisons are not valid, however, since in the lymphocyte assay one is also examining the specificities of cells that were not stimulated to produce anti-AMP antibodies by $(AMP)_2$–gramicidin S. We know from our previous studies[5] that A-ovalbumin stimulated at least a hundredfold more clones than did $(AMP)_2$–gramicidin S. These additional cells should also bind AdGase and have different spectra of cross-reactions.

Our data support the notion[2] that combining sites of antibodies are multispecific. Thus, they share the property of other ligand-binding proteins (such as enzymes) of being able to bind more than a single ligand. Like enzymes, they can bind ligands of diverse structure, and, again, as with enzymes, effective ligands need have no obvious resemblance to the primary 'specific' ligand (see, for example, ref. 11). Antibody-combining sites can be large enough to accomodate five or six sugar residues[12]. The contact surfaces, therefore, are complex. One would not expect to be able to predict the types of different structures that can be accommodated. Indeed, our results show that predictions are not feasible. Our anti-AMP antibodies do not bind GMP, UMP or TMP well. Yet, they bind such molecules as menadione and hydralazine. With respect to the former, we have carried out preliminary studies to determine the types of forces involved in its binding to fractions A and B. Surprisingly, its ability to bind decreased markedly with temperature indicating that hydrophobic forces are not predominant[13]. AMP, on the other hand, bound equally as well at 0 °C and at 37 °C, suggesting that hydrogen bonds, electrostatic forces and hydrophobic forces might all be involved in its binding to specific antibody.

Table 3 Haemolytic assys with hapten-coated sheep erythrocytes*

	% Lysis of coated sheep erythrocytes†			
	.Anti-AMP			
Hapten	Fraction A	Fraction B	Fraction C	Anti-A ovalbumin
Adenosine	100 (1:16)‡	100 (1:8)	100 (1:8)	100 (1:640)
DNP	45	81	16	100 (1:64)
Menadione	60	24	0	100 (1:32)

*DNP-erythrocytes: 2,4-dinitrobenzene sulphonic acid (sodium salt; Eastman) in 1.0 ml PBS was added to 1.0 ml 5% suspension of sheep erythrocytes in PBS. The suspension was left at room temperature with intermittent shaking for 2 h. Excess reagent was removed by washing several times with PBS. Menadione-coated erythrocytes: A saturated solution of menadione was made up in PBS. A 5% erythrocyte suspension (1 ml) was exposed to 5 ml of the saturated solution for 30 min, followed by two washings with PBS.

†Haemolytic assay carried out as described in Table 2. Quantification of haemoglobin released from lysed erythrocytes was carried out by adding 1 ml PBS to each testtube after the second incubation period. The supernatant was recovered by centrifugation at 150*g* for 5 min at 4 °C and haemoglobin was determined spectrophotometrically at 413 nm. Haemoglobin released by cells lysed by distilled water represented 100% lysis.

‡Numbers in parenthesis denote highest dilution of antibody that caused lysis; otherwise, antibody was undiluted and was at concentration of about 200 μg ml^{-1}. Uncoated sheep erythrocytes + antibody and coated erythrocytes with pre-immune sera showed no lysis.

Although we think it likely, our data cannot be used to show that different subsites of the combining site are involved in the binding of various ligands. We would like to establish this with certainty by attempting to isolate sufficient antibody protein to attempt

Table 4 Inhibition of binding of AdGase to lymphocyte surface receptors by various inhibitors

Inhibitors (20 nmol)	% Inibition†
AMP	28 ± 3
Menadione	31 ± 3
Hydralazine	28 ± 3
Sodium barbital	20 ± 2
Caffeine	12 ± 1
GMP	7 ± 1
DNP–glycine	2 ± 1
Procaineamide	0
UMP	0

The assay procedure was a modification of one described previously[10]. Peripheral blood lymphocytes (2×10^6 in 50 μl PBS) were incubated with 20 nmol ligand in 25 μl PBS at 4 °C. After 90 min, 50 μl of a 1:1000 dilution of AdGase were added and incubation was continued at 4 °C for another 3 h. PBS (2 ml) was added to each sample and the cells were collected on 25-mm diameter Whatman No. 1 filters placed in a Millipore manifold. A 1:1000 dilution of AdGase (50 μl), without cells, was also filtered through the paper to serve as a blank. All filters were then washed with 20 ml PBS and placed in test tubes containing the assay solution described previously (footnote to Table 1) and incubated for 30 min at 25 °C in a shaking water bath. All subsequent procedure described previously[10].

†Given as mean ± s.d. mean of four experiments done in duplicate.

crystallisation and X-ray crystallographic examination. This is not necessarily a trivial point since it would definitely rule out the possibility that all competing ligands resemble each other sufficiently to explain the crossreactions. For example, Michaelides and Eisen[14] used this argument to explain cross reaction between menadione and DNP in myeloma proteins. This is a very difficult argument to dispose of, since interactions between ligands and binding proteins take place mainly by way of functional groups and/or hydrophobic surfaces. There are only a limited number of the former, and very many ligands have hydrophobic areas. Thus, we can always find structural resemblances, particularly with small ligands. Each of our three purified AMP-binding proteins, however, has its own cross specificities, a finding that would not have been expected if there were thermodynamically important structural similarites among the ligands. The finding that each of the anti-AMP proteins bound a different spectrum of other ligands is in agreement with the proposal of Richards *et al.*[2] that the high specificity of the immune response lies not only in the properties of a single antibody molecule but is due also to the production of a heterogeneous population of antibody molecules all sharing specificity for AMP (as we found with A-ovalbumin as an immunogen)[5] but with each member having its own spectrum of crossspecificities.

Internal motions of antibody molecules

ANTIBODY molecules of the IgG class are composed of three covalently linked regions[1,2]. Two of these (designated Fab) are identical and bind antigen; the third (Fc) has been identified as the site of antibody effector functions (for example, complement fixation), which are activated by antigen binding[3]. There is evidence that the binding of antigen to the Fab region induces an allosteric transition in IgG and that this transition may be a step in the effector activation process[4]. The findings of Pecht *et al.*[5] indicate that for complement fixation both Fab regions must bind antigen, even though binding to one induces some conformational change in Fc. Binding of hapten does not lead to complement fixation in general, but some exceptions to this rule are known[6]. The interchain disulphide bridges must be intact for Fab ligand binding to have a productive effect on the Fc region[7,8]. Both the Fab and Fc regions have a domain structure; each consists of a pair of compact lobes covalently linked by strands of polypeptide chains[9]. A schematic diagram of the connectivity of the IgG lobes is given by Padlan[10]. One of the fundamental questions involved in antibody function is the nature of the mechanism by which binding of antigen to the Fab regions affects the Fc region. Huber *et al.* have recently outlined a possible allosteric model for the activation step on the basis of X-ray and other data[9]. In this note we use simple diffusion arguments to estimate the characteristic times associated with the Huber proposal. Since the analysis deals only with the relative motion of the IgG domains, it is possible that slower intradomain structural changes are also involved in the activation process; if so, the estimated characteristic times would be lower bounds for the activation time. The role of conformational transitions in effector function activation is still in dispute[11], but we note that the diffusional model may be useful for analysing other dynamical phenomena in immunoglobulins, such as their fluorescence depolarisation behaviour[12–14].

Huber *et al.*[9] assume that the lobes have relatively little interaction with each other in the unliganded IgG. Thus, neighbouring lobes are free to rotate relative to each other over certain angular ranges. Inspection of the Fab regions in the IgG structure suggests that the V_L–V_H dimer (the antigen-binding lobe) can rotate about an axis passing through the 'switch peptides' which connect it to the C_L–C_H1 dimer (the second lobe in Fab); this motion has been termed 'elbow bending'. The Fab region itself can rotate relative to the Fc region by a 'hinge bending' deformation of the peptide which links the C_L–C_H1 dimer to C_H2–C_H2, the first lobe of the Fc region. Although the 'elbow' and 'hinge' bending motions are the only ones that concern us here, it should be noted that there may also be a flexible link between the two Fc lobes.

The binding of antigen is postulated to trigger the successive 'locking' of some of these bending motions[9]. In particular, it is suggested that antigen binding induces a conformational transition in the V_L–V_H dimer that causes it to interact more strongly with the C_L–C_H1 dimer. This interaction is assumed to induce a conformational transition in the C_L–C_H1 dimer that alters its affinity for the C_H2–C_H2 dimer. The resulting coupling between the Fab and Fc regions is presumed to lead to the activation of Fc.

The relative displacements of the various domains in going from the open (unliganded) to the locked (liganded) structure can be characterised as bending motions. We assume in what follows that these bending motions can be described by a one-dimensional diffusion equation. The justification for this assumption comes from a recent theoretical study of the hinge bending mode in lysozyme[15]. It was found there that in spite of the forces due to the interactions between the two lobes (covalent plus non-bonded), their relative motion is diffusive in character; that is, the hydrodynamic frictional forces dominate the motion. Frictional effects are likely to be even more important in the relative motion of the IgG lobes, which are larger than those in lysozyme and apparently interact more weakly.

The one-dimensional diffusion equation is

$$\frac{\partial p}{\partial t} = D\frac{\partial^2 p}{\partial \theta^2}$$

where $p(\theta, t)$ is the probability that the elbow or hinge angle is θ at time t and D is the angular diffusion constant appropriate to the particular motion. The boundary conditions are $p(0, t) = 0$, representing locking at the angle $\theta = 0$, and $\partial p/\partial\theta = 0$ at $\theta = \theta_r$, corresponding to reversal of the bending motion at the maximum excursion angle, θ_r. If all bending angles between 0 and θ_r are equally populated initially, the average time required to reach $\theta = 0$ is $\tau = \theta_r^2/3D$ (ref. 16); in the limiting case that all molecules have $\theta = \theta_r$ initially, the average time becomes $\tau = \theta_r^2/2D$.

To obtain approximate values for the angular diffusion constants, we model the domains involved by spheres of radius a and treat the bending motions as relative rotations about an axis located a distance r from the sphere centres. The effect of the fluid environment is represented by using the Stokes law for the frictional coefficient of the spheres[17]; the correction factors for relative motion and hydrodynamic interaction approximately cancel for rough spheres which are close together[18]. The calculated diffusion constants in water at 300 K ($\eta = 1\times10^{-2}$ P) are $D_e \approx 2.8\times10^7$ s^{-1} for the elbow bending ($a \approx r \approx 20$ Å) and $D_h \approx 3.4\times10^6$ s^{-1} for the hinge bending ($a \approx r \approx 40$ Å).

To complete the estimate of the average times required for locking, we need to know the ranges of angular excursion, θ_r. If we use the angular differences between the 'minimum disorder' unliganded IgG structure and the hypothetical liganded structure proposed by Huber *et al.*[9], they are $\theta_r \approx 0.7$ rad (40°) for the elbow, and $\theta_r \approx 0.5$ rad (30°) for the hinge. The resulting average time for elbow locking is $\tau_e \approx 6\times10^{-9}$ s and that for hinge locking is $\tau_h \approx 3\times10^{-8}$ s.

It is possible to test the diffusion constant values by using them to analyse fluorescence depolarisation results for antibody molecules[12,13]. We consider a large molecule with isotropic rotational diffusion constant D_{IgG} to which a labelled internal rotor with uniaxial rotational diffusion constant D_h is attached. If the angular range of internal rotation were unrestricted, the fluorescence anisotropy of the label would be a sum of exponentials, each decaying with a certain characteristic time; the characteristic time for the fastest decaying term would be $\phi_h = 1/(6D_{IgG}+4D_h)$ (ref. 19). This expression should also provide a useful estimate of the decay time due to Fab motion in IgG, although the range of internal motion is somewhat restricted in this case. Taking $6D_{IgG} = 1/(1.7\times10^{-7}$ s) from the work of Yguerabide *et al.*[12] yields $\varphi_h = 5.1\times10^{-8}$ s, which is near the shortest decay times measured for antibodies labelled with fluorescent haptens (3.3×10^{-8} s) (ref. 12). Thus, these results indicate either that Fab–Fc locking is somewhat less rigid in liganded antibody than supposed by Huber *et al.* or that hapten is less effective than antigen in inducing the Fab–Fc locking; circular polarised fluorescence studies support the latter possibility[5]. It is worth noting that the shortest decay times measured in similar studies using nonspecific, covalently bound labels are somewhat smaller (10^{-8} s); (ref. 13) this corresponds to the estimated shortest decay time for a labelled V_L–V_H dimer of a completely open IgG: $\varphi_e \approx 1/(6D_{IgG}+4D_h+4D_e) \approx 8\times10^{-9}$ s. This suggests that it is not necessary to invoke independent rotation of the fluorophore to explain the short relaxation time measured by Wahl[13]. The above results, taken together, lead to the interpretation that specific binding of hapten may reduce motion about the elbow without a comparable effect on motion about the hinge, while nonspecific attachment of labels has little effect on either motion. Thus, the fluorescence depolarisation studies are consistent with a hydrodynamic model of IgG internal motions.

A number of possible refinements of the model calculations should be considered. Although the times involved in the relaxation phenomena and the locking reaction are not expected to be very sensitive to the detailed form of the elbow and hinge bending potentials (which we have assumed to be constant in the region $0 \leqslant \theta \leqslant \theta_r$ and infinite outside), the locking times do depend quadratically on the allowed ranges of motion. In particular, the hinge bending motion could involve a larger angular range in the unliganded antibody than assumed above. This would lead to a longer average locking time; a reasonable upper estimate for θ_r ($\theta_r = 90°$) gives $\tau_h \approx 2.5\times10^{-7}$ s. Another factor to be considered is that the diffusion constants D_e and D_h would be decreased by the binding of large antigens to the IgG. If the bending motions were to depart somewhat from the assumed one-dimensional rotational character, the conclusions of this work would not be altered significantly. If the probability of locking were less than unity at $\theta = 0$, the required correction factor could be introduced by using a partially absorbing barrier[20]. Finally, the detailed character of the bending potentials and their role in the bending motion and the locking reaction are of considerable interest.

Are late replicating regions in polytene chromosomes of *Drosophila* enriched by repeated nucleotide sequences?

THE ordered highly coordinated pattern of replication of different bands is characteristic of salivary gland chromosomes of *Drosophila*[1,2]. During the initial stage of polytene chromosome replication labelled precursor is found over Puff/interband sections while prominent bands incorporate label later and need in general a longer time for DNA synthesis[3,4]. It is significant that regions of ectopic pairing in the chromosomes of *D. melanogaster* are of the late replicating type. We report here that late replicating DNA from *Drosophila* salivary gland cells reassociates after denaturation more rapidly than the bulk of the DNA from the same cells A high level of repeated nucleotide sequences may be involved.

Several autoradiographic investigations have shown that there is no strict correspondence between DNA content and replication time of chromosome bands[5,6]. In other words, it is not possible to explain the difference in the timing and duration of replication of regions studied based only on different DNA content. Thus there are at least two possibilities to explain the prolonged S-phase characteristic for definite regions in the genome of *Drosophila*:

(1) The macromolecular configuration of DNA packed into chromomers in different parts of the genome determines the number of initiation points and consequently the time necessary for the replication of a given band. Thus regions of prolonged replication may have fewer initiation sites in their DNA.

Table 1 Frequencies (%) of different labelling types at the end of third instar in *D. virilis* larvae

Time from the beginning of third instar (h)	70	72	74*
Total no. of nuclei studied	1,064	791	584
No. of labelled nuclei	284	164	96
Frequency of continuous replication pattern (%)	10.6	2.4	2.1
Frequency of discontinuous replication pattern 89.4 (final stages of S-phase) (%)	89.4	97.6	97.9

* Larvae with dark-brown anterior spiracle stage used in this investigation.

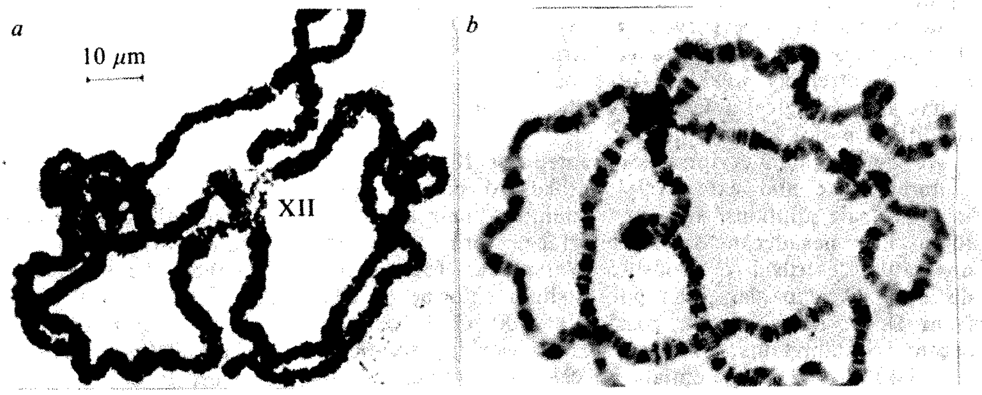

Fig. 1 *a*, Polytene chromosomes of *D. virilis* after long-term labelling; (first series) (bar represents 10 μm); *b*, polytene chromosomes of *D. virilis* after short-term labelling. Only prominent late replicating bands incorporate ^{3}H-thymidine.

(2) Late replicating regions (bands) of polytene chromosomes may be enriched by repeated nucleotide sequences. This possibility comes to mind because C-heterochromatin consisting of highly repetitive satellite DNA (sDNA) is a late replicating fraction of the genome in various organisms.

To examine the latter possibility we studied renaturation kinetics of salivary gland DNA of *D. virilis* labelled by different methods. A long-term labelling was carried out in the first series of experiments. The flies were reared from oviposition to the end of third instar larvae on a medium containing ^{3}H-thymidine (100 μCi ml^{-1}, specific activity 4.4 Ci mmol^{-1}). The salivary gland chromosome DNA of such individuals undergoes several replication cycles in the presence of labelled precursor and is thus uniformly labelled (Fig. 1*a*). In a second series of experiments (short-term labelling) the salivary glands of third instar larvae (dark-brown anterior spiracle stage) were incubated for 15 min in a drop of Ringer insect medium supplemented with ^{3}H-thymidine (100 μCi ml^{-1}, 49 Ci mmol^{-1}).

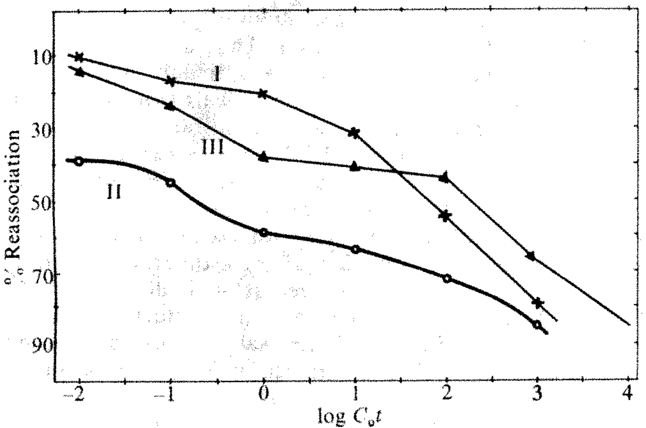

Fig. 2 Renaturation kinetics of *Drosophila virilis* salivary gland DNA labelled by different methods (I, II) and mouse DNA used as standard (III) as measured by hydroxylapatite chromatography. Samples of sheared labelled DNA were sealed in glass capillary tubes, heated to 105 °C for 10 min to denature the DNAs and then incubated at 60 °C to allow renaturation. At various times samples were removed, diluted into 1 ml of 0.12 M PB and frozen for subsequent hydroxylapatite fractionation. Single-stranded and double-stranded DNAs were eluted with ten times the bed volume of 0.12 and 0.5 PB, respectively. Renaturation was measured by ^{3}H-radioactivity of the hydroxylapatite fractions. I, *D. virilis* salivary gland DNA-long-term labelling (X). II, *D. virilis* salivary gland DNA-short-term labelling (○). III, Mouse DNA (standard) (▲).

In preliminary experiments, after short-term labelling of salivary glands from these larvae, 98% of labelled nuclei showed discontinuous labelling patterns characteristic of end phases of polytene chromosome replication (Table 1). Thus preferential labelling of DNA of late replicating regions (bands) occurred in these experiments.

Discontinuously labelled chromosomes of the final stage of the S phase are shown in Fig. 1*b*. DNA from salivary glands was isolated using the cetavlon procedure[7]. DNA was sonicated and dissolved in 0.12 M Na-phosphate buffer (PB). The average fragment size of the sonicated material is about 300–400 nucleotides.

The reassociation kinetics of DNA from both series of experiments were studied using hydroxylapatite chromatography. Comparison of C_0t curves of both DNA preparations (I, II series) shows that late replicating DNA (series II) reassociates at a faster rate than the bulk DNA (series I) and hence contains significantly more repeated sequences than the genome as a whole.

The difference observed could not be due to the late replication of sDNA which does not replicate during polytenisation or at least does not replicate as frequently as euchromatic sequences[8].

The high value of reassociation at $C_0t = 10^{-2}$ in the case of late replicating DNA (series II) can not be due to snap back of palindrom sequences. Zero-time reassociation in series II equals 7%, compared with 3.8% in series I.

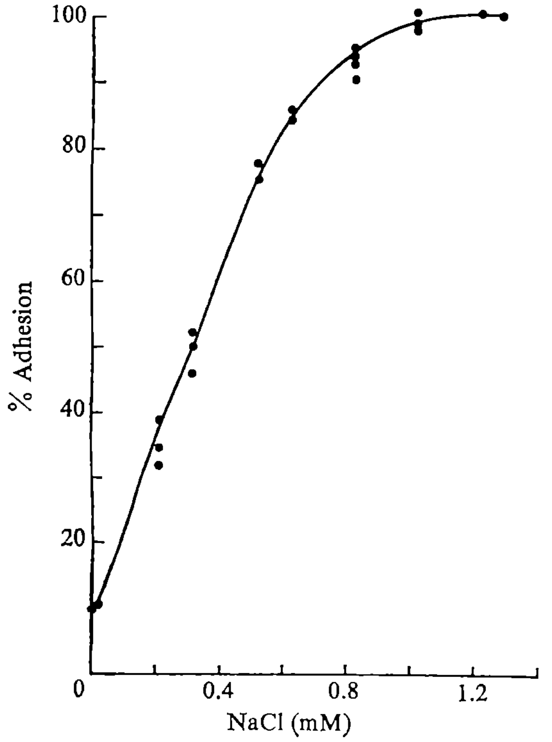
Long-range attraction between red cells and a hydrocarbon surface

WE present here experimental evidence that adhesion of red cells to an oil–water interface is mediated by an attractive force acting at a distance apparently exceeding 100 nm. Although long-range forces have recently been measured between bilayer lipid lamellae in water[1] and attraction between cells has been inferred from aggregation studies[2,3], the long-range nature of attraction in cell studies has previously been an assumption rather than a deduction from experimental evidence. Our analysis strongly implicates a long range attractive force, but this force is extremely weak at large distances and whether it has any biological role in cell adhesion in physiological conditions is not known.

We used human erythrocytes treated for 18 h in 3.3% glutaraldehyde and extensively washed, to prevent lysis in dilute salt solutions, and then examined their adhesion to a flat hexadecane–saline interface, formed in an apparatus described previously[4]. Water was four times distilled, twice in glass, and pure sodium chloride (a gift from Dr J. Mingins) was roasted at 700 °C to remove organic contaminants. The final *p*H of working solutions was 5.4±0.1. The ζ-potentials of cells and sonicated oil droplets in saline were measured in a Zeiss cytopherometer modified for low constant currents. Surface tension of method in a thermostatically controlled apparatus (±0.1 °C). Adhesion was assessed by allowing cells to sediment under gravity in salt solution onto the oil–water interface for 20 min, then inverting the whole system (oil uppermost). The number of adherent cells was recorded photographically, the total initial number counted at the interface being greater than 400 in every case. Results were unaffected by increasing settling time to 1 h before photography.

From 145-mM NaCl down to 1.0 mM, cells remained attached to the interface indefinitely after inversion; below 1.0 mM, cells fell away from the interface (see Fig. 1). In another series of experiments cells were allowed to attach to the interface either at 10 mM or at 0.4-mM NaCl, then the system was inverted and the saline was carefully exchanged for distilled water. Between 70% and 90% of the cells fell off, whereas none lost their adhesion in a control where exchange was done with 0.4-mM NaCl. Since the control excludes mechanical removal we conclude that most of the cells in dilute saline are reversibly attached. We tested for contamination of the oil–water interface by adherent cells by measuring the interfacial tension of a drop of 10 mM or 150 mM saline formed under hexadecane. When the saline contained cells which were allowed to settle onto the interface for 20 min the surface tension remained the same as for a drop lacking cells, to within our experimental accuracy of 0.1 dyn cm^{-1}. Red cells untreated with glutaraldehyde caused a rapid large fall in interfacial tension. We conclude that glutaraldehyde-treated cells did not contaminate the interface.

Fig. 1 Adhesion of red cells to hydrocarbon as a function of salt concentration.



In 0.3-mM NaCl where half the red cells fall off the interface, the interface has a potential of about −30 mV and the cells −95 mV. By modelling the biconcave red cell as a torus we calculate the electrostatic repulsion for a cell interacting *en face* with the interface (as most are seen to do). We combine the computational procedures of Alamov[5] and Brenner and Parsegian[6] using the full non-linear Poisson–Boltzmann (PB) equation in the region where potentials exceed 25 mV. The validity of the PB equation for force calculations has recently been verified in two ways[7,8]. We take[9] the smaller toroidal diameter as the red cell thickness (~1.5 μm), the length of the toroidal axis or Pappus line as 17 μm, the density in water as 0.096 g ml^{-1} and red cell volume as 85 μm^3. Such an average cell would experience a gravitational force of 8×10^{-9} dyn. This is the size of the calculated electrostatic repulsion in 0.3-mM NaCl for a cell to interface separation of about 240 nm, that is, conditions in which an average cell is about to lose its adhesion. Thus a cell sedimenting down onto the oil–water interface under gravity alone cannot approach closer than 240 nm. This conclusion is the crux of our argument. Without an attractive force, cells would balance at 240 nm and fall off on inversion Because half the population do not, an atractive force must reach out to at least 240 nm. To take account of the population spread, the calculation was done for conditions corresponding to 20% and 80% adhesion, giving estimates of the range of attractive force that can act at such distances is the van der Waals or electrodynamic charge fluctuation force.

Whether adhesion in dilute salt occurs at a finite separation as a result of a balance of long-range attraction and electrostatic repulsion or takes place at 'molecular contact' is not directly ascertainable from our measurement. Reversibility of adhesion is consistent with the action of long-range attractive forces In the absence of a mathematical expression for electrodynamic attraction between a torus (or cylinder) and a plane wall which is valid for large separations where retardation will be important, one can only say that the attractive force must decrease with increasing distance. From what is known of the strength of van der Waals forces (1) (7) (10) (11) it seems virtually impossible that an electrodynamic force could pull cells in 0.3-mM NaCl into molecular contact with the interface; a force balance at a finite separation seems inescapable. This conclusion is supported by interferometric observations (in progress) on cells adherent to the interface in 0.4-mM NaCl. Adherent cells can oscillate in a direction perpendicular to the interface while remaining separated from it by a finite gap. This behaviour is not consistent with molecular contact but is precisely what would be expected from a long-range force balance.

Detection of long-range attraction is of considerable interest from a physical viewpoint, but its biological significance remains uncertain.

The number of turns in globular proteins

Peptide chain turns are those parts of a globular protein where the backbone is folded back upon itself. We show here that the number of turns is a linear function of the number of amino acid residues in the protein, and we compare the two contrasting models for turn formation. In a sequence-dependent model, turns are a linear function of the molecular weight, while in a shape-dependent model, they are a function of the two-thirds power of the molecular weight. But, a shape-dependent model also behaves, to a good approximation, as a linear function within the domain of interest. We suggest some consequences of this work for protein folding.

Peptide chain turns were first identified by Kuntz[1] and by Lewis *et al.*[2]. Kuntz points out that turns are important for two reasons—they constitute recognisable structural units in proteins, and they are situated at the solvent accessible surface of the molecule. Rose and Seltzer[3] devised an algorithm to identify peptide chain turns from coordinate data. This algorithm treats the polymer chain as a curve in space and computes a discrete radius of curvature for that curve. A turn corresponds to a locus where the chain direction vector is changing rapidly and the value of the radius of curvature is at a local minimum. Although turns can be shown to correspond to local minima in the radius of curvature, the correspondence is not 1:1; that is, some minima are not associated with turns, and additional analysis is developed to identify these loci. α-Carbon coordinate data are the only information required by the algorithm, and notions about hydrogen bonding at turn loci are irrelevant to the geometric nature of the procedure. In this sense, the algorithm provides an objective criterion for the recognition of turns as strictly structural components in proteins.

We have used the algorithm for turns to discover the number of turns in each of 21 proteins ranging in size from 53 to 450 amino acid residues (Table 1). A least squares analysis shows that the number of turns (T) is a linear function of the number of amino acid residues (R) as given by

$$T = 0.125R + 2.28 \qquad (1)$$

The correlation coefficient is 0.983. An equivalent correlation exists between T and the molecular weight of the protein. These data are shown graphically in Fig. 1. The analysis is especially compelling in view of the strictly structural nature of the procedure.

We have previously defined a structural segment as the three-dimensional structure assumed by a continuous sequence of linear chain neighbours bounded by consecutive chain turns[5]. Clearly identification of the turns also results in identification of the structural segments, with the number of segments always one greater than the number of turns. A structural segment, by this definition, is similar to Chothia's definition[4] of pieces of secondary structure. Thus, the number of structural segments (S) is also a linear function of the number of amino acids as given by

$$S = 0.125R + 3.28 \qquad (2)$$

Some discussion of the linear nature of the function relating turns to the number of residues is in order. In particular, a class of functions of the form

$$T = aR^n + b \qquad (3)$$

can be studied where, of course, $n = 1$ when the relationship is a linear one. A choice of $n = 2/3$, however, is appropriate to the geometric argument proposed by Kuntz[1], and it turns out that the data in Table 1 will fit such a model equally well. Indeed, given suitable coefficients a and b, models of the form given in equation (3) seem to be quite insensitive to a choice of n over the domain 0.5–1.5.

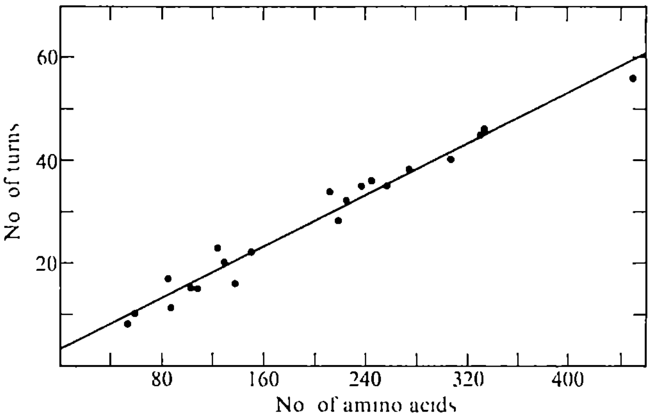

Fig. 1 A plot of no. of turns against no. of amino acids for 21 proteins. The least squares line through these points has slope 0.1245. Detailed data are given in Table 1.

To resolve the value of n, a log–log logarithmic plot of turns against number of residues was constructed. The slope of the least-squares line to these data is 0.94, much closer to linearity than to 2/3.

Two distinct models for turn formation emerge from the above discussion. A sequence-dependent model results if turns are determined by linearly local sequences of amino acids along the polypeptide chain. For a given protein with k sites for turns imbedded within the amino acid sequence, the fraction of total residues in turns would be k/R. The data in Table 1 show that k/R is reasonably constant over a large and diverse sample of globular proteins, a fact that can be attributed to the characteristic composition of globular proteins in general[10]. For this reason, the data points of Table 1 cluster well around a line with a slope that is the best-fit to the values of k/R as shown in Fig. 1. The sequence-dependent model is also consistent with the success of empirical correlations between sequence and structure[11]. The model is inherently linear, with $n = 1$ in equation (3).

In contrast, a shape-dependent model would result if turns were distributed over the globular surface of the folded protein, without particular regard for sequence. Janin[12] and Teller[13] have shown that the surface area of proteins is proportional to the molecular weight raised to the two-thirds power. Hence, a shape-dependent model with a uniform density of turns would have $n = 2/3$ in equation (3).

For the reasons given, a sequence-dependent model seems more likely, and the insensitivity of equation (3) to a choice of n implies that sequence-dependent behaviour need not be at the expense of the protein's globularity. Another way of seeing this is to consider the surface-to-volume ratio for spheroids of interest, as shown in Fig. 2. Within the size range of proteins, this ratio is nearly constant, and approximately the same for either a sphere or prolate and oblate spheroids with axial ratios of 2:1. That is, the equation

$$A/V = c \tag{4}$$

where A is the surface area, V the volume, and c a constant, is a good approximation over the domain of interest. Since the number of residues in the protein is certainly proportional to the molecular weight which is, in turn, proportional to the volume, a sequence-dependent model will vary linearly with the volume of the protein

$$\text{Turns} \propto V \tag{5}$$

while a shape-dependent model will vary linearly with the two-thirds power of the volume or the surface area

$$\text{Turns} \propto A \tag{6}$$

From equation (4), however, $A = cV$, so the shape-dependent model is also seen to vary linearly with the volume. Thus, within the size range of interest, even a shape-dependent model behaves, to a good approximation, as a linear function of the number of residues.

If geometric criteria alone determine the turns, it is unlikely that any protein of globular shape would deviate very much from the shape-dependent model; while if the local sequence determines turns, a protein of usual composition would be expected to exhibit deviations. Myoglobin is a case in point. Equation (1) predicts 21 turns for the 153 residues of myoglobin, but the algorithm for turns finds only 13. A sequence analysis of myoglobin confirms the unusual composition of this protein which gives rise to unusually long helical structural segments with few turns.

The apparent sequence-dependence in our findings was inferred from counting structural sites in the folded protein. The fact that locally determined, sequence-dependent sites are still discernible after folding can be interpreted to mean that the protein is partitioned into its structural segments and turns by local sequences of amino acids, and that these moieties tend to persist. This interpretation is compatible with our model of protein folding[6], called the LINCs and hinges model. In this model, linearly short and medium range interactions dominate early folding, causing the disordered chain to assemble first into local independently nucleated continuous segments (LINCs). LINCs are structurally persistent, separable, modular entities that are precursors to their counterparts in the folded protein, and each LINC has its own characteristic equilibrium between random coil and the conformed state. The hinges are viewed as conformationally permissive loci where the backbone changes its overall direction; it is presumed that these become chain turns.

Table 1 No. of turns measured and predicted for 21 proteins

Protein	No. of amino acids	No. of turns (measured)	No. of turns (predicted)
1 Carbonic anhydrase	258	34	34
2 Carboxypeptidase	307	39	41
3 Chymotrypsin	245	36	33
4 Concanavalin A	237	34	32
5 Cytochrome b5	87	10	13
6 Cytochrome C	103	14	15
7 Flavodoxin	138	15	19
8 Glyceraldehyde-3-phosphate dehydrogenase	334	45	44
9 Hexokinase	450	55	58
10 High potential iron protein	85	16	13
11 Lactate dehydrogenase	331	44	44
12 Lysozyme	129	19	18
13 Myogen	108	14	16
14 Papain	212	33	29
15 Phosphoglycerate mutase	218	27	29
16 Ribonuclease S	124	22	18
17 Rubredoxin	53	7	9
18 Serine protease (fragment)	225	31	30
19 Superoxide dismutase	151	21	21
20 Subtilisin	275	37	37
21 Trypsin inhibitor	58	9	10

Measured turns are found with the algorithm of Rose and Seltzer[3]; these are the data points in Fig. 1. Predicted turns are calculated from equation (1) which gives the best-fit line shown in Fig. 1. The difference between measured and predicted values is the residual for each protein data point.

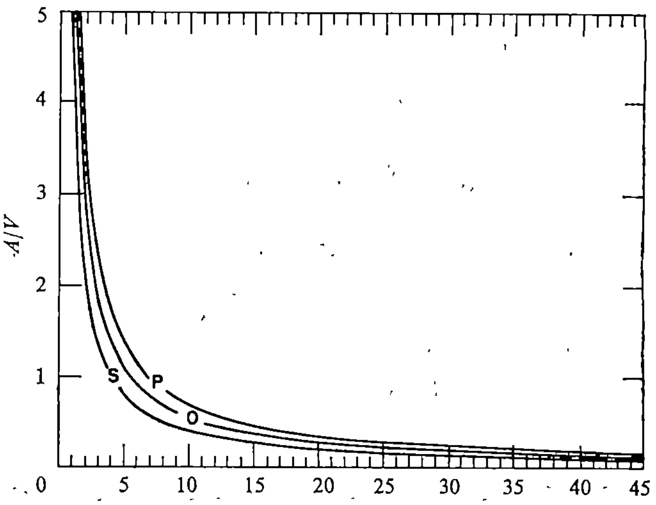

Fig. 2 A plot of the surface-to-volume ratios for a prolate ellipsoid with axial ratio 2:1 (P), an oblate ellipsoid with axial ratio 2:1 (O), and a sphere (S). The abscissa is the radius of the sphere and the length of the major axis of the other spheroids. Assuming a partial specific volume of 0.75 $\text{cm}^3\ \text{g}^{-1}$ and a perfectly spherical shape, rubredoxin would have a radius of 12 Å and LDH would have a radius of 22 Å.

In our folding model, a protein is comprised entirely of LINCs and interspersed hinges. These nascent structural elements then coalesce as a result of orientation and diffusion processes to provide a cooperative mutual stabilisation. The cooperative folding of LINCs is responsible for the emergence of larger structural domains, and, ultimately, the native structure of the protein. Not until the LINCs have coalesced into larger structures does the protein take on its characteristic interior and exterior or its overall globular character. Similar folding models have been proposed by other groups[7-9,14].

We thank Professor D. Dennis for discussion and comments, Dr Richard Feldmann for atomic coordinate data and Professors K. E. Van Holde and R. H. Winters for their interest. This work was supported in part by USPHS Grant 7ROIGM23713.

Complexes & First Row Transition Elements
D. NICHOLLS

An introductory text for students making their first detailed study of transition element chemistry. It concentrates on the first member of each group, since their properties differ significantly from those of subsequent members. The first part of the book deals with the chemistry of complexes—a topic of central importance to the study of transition elements. Throughout the text emphasis is placed on the properties and reactions of metal aquo-ions and the donor-acceptor properties of transition metal compounds.

£3.95 paperback

The Heavy Transition Elements
S. A. COTTON AND F. A. HART

A detailed account of all the transition elements except the first row (3d series). The book features a discussion of lanthanides and actinides, with emphasis on recent advances in their structural chemistry.

hardcover £8.95 paperback £4.95

Galaxy Formation
John Gribbin

A personal view of galaxy formation – a subject which holds a central place in modern astrophysics. The book reflects the author's own interests in this field, and thus offers a new and different perspective to a fascinating topic. Formal mathematics is kept to a minimum and the general level of the text makes it suitable for the second year physics students at university.

Contents: Stars and Galaxies-Cosmology: The Expanding Universe – The Traditional Approach: Turbulence and Gravitational Instability – Layzer's Gravitational Clustering Hypothesis – Ambartsumian's Fragmentation Hypothesis – Continual Creation – Newtonian Cosmology and Jean's Criterion – The Retarded Core Hypothesis – The Growth of Irregularities in an Expanding Universe – The Evolution of Galaxies – Our Galaxy – The Present Balance and Future Prospects.

Wealth of data on pulsars

S. Jocelyn Bell Burnell

Pulsars. By F. G. Smith. Pp. 239. (Cambridge University: Cambridge, London, New York and Melbourne, 1977.) £9.50.

THE tenth anniversary of the discovery of pulsars occurs later this year and at last the spate of papers seems to be slackening. It is a good time to produce a book on pulsars and we must be grateful to Professor Graham Smith for taking the trouble to do so. This book aims to be a summary and a review of the subject and is at a level suitable for research students in the field, or more senior scientists from other branches of astronomy who wish to have a reference book on the subject.

Its emphasis is mainly on the wealth of observational data that now exists on pulsars, with enough of the theoretical work included to give an idea of how well it all fits together. (It doesn't.) It describes phenomena rather than the theories which are current. There are some topics which the stranger to the subject might not expect to find in a book with this title—for example, several chapters on the interstellar medium, and some X-ray astronomy too. But they are rightly included. I have seen the contents page of another book on pulsars to be published later this year in the USA and it is very striking how similar both these books will be in the topics they choose to consider. Not only is it felt elsewhere too that the time is right to write this sort of book, but the scope of a book on pulsars is clearly determined by the state of the subject today.

The state of the subject is a mass, perhaps an embarrassment, of diverse observational results. The phenomena observed in pulsars are now well authenticated, although it is still hard to see whether differences are differences of degree or differences of kind. Our understanding as to *why* pulsars are as they are is much more restricted, and it could be some years hence before theoreticians solve some of the horrible problems presented by pulsars. Meanwhile, observers are anxious to find the critical experiments that should be made.

Although the pace has slackened, there have been some significant developments over the past few years which the author deals with in a variety of ways. For example, the recent conclusion that there is an embarrassingly large number of pulsars to have been formed in supernova explosions gets mentioned a few pages from the end; but throughout most of the book the impression is given that this is undoubtedly the way neutron stars are formed. (In fact one general criticism is that sometimes Professor Smith makes what may be tentative conclusions sound too established.)

The sections on X-ray observations of neutron stars have suffered most. The whole subject is changing very rapidly; even while writing the book Professor Smith admits he had trouble keeping up with it! A couple of years later these sections look very sorry. It must be difficult to judge how and where to draw the line when writing a book containing such material, but one option is not to attempt to include it in any detail. A similar restraint has been necessary until recently on the whole subject of pulsars.

One would like to recommend this book to a new research student but, although I warmly commend the radio astronomy (the greater part of the book), I would feel obliged to warn him that the X-ray and γ-ray sections are not to be relied upon as accurate accounts of the subjects. There are a number of misprints in the book as a whole which would drive a research student to exasperation, but sorting them out could be quite an educational process in itself. The index on occasion drove me to exasperation. (No Poincaré sphere, Professor Smith!)

The book is very readable with an informal style; it is a welcome compendium of the work that has been done by radio astronomers on and with pulsars. Many of us will find it a useful book for ourselves or others to refer to. We have had to wait a long time for it. ☐

S. Jocelyn Bell Burnell is a research fellow at the Mullard Space Science Laboratory, University College, London, UK.

Decade of the mouse

Development in Mammals. Vol. 1. Edited by Martin H. Johnson. Pp.386. (North-Holland: Amsterdam, New York and Oxford, 1977.) $34.50.

Now that the genetic code has been not only cracked but put to work, the last major uncharted territories of biology are usually reckoned to be the brain and development. The earlier years of the century saw a series of classical experiments on the embryology of invertabrates—for example, sea-urchins and lower vertebrates, in particular amphibians. The past ten years have been the 'Decade of the Mouse'. A wide sweep of technical advances—biochemical, biophysical, microsurgical, and above all advances in the techniques of *in vitro* culture—have rendered the mammalian embryo accessible for the first time to sophisticated analysis. The rapid strides that have been and are being made in our understanding of mammalian development, at the level of mechanisms as well as description, render the field immensely exciting to those of us working in it.

It is therefore timely that a new review series, *Development in Mammals*, has been launched. The editor is Martin Johnson, well known for his personal contribution to our understanding of the immunology of early mammalian embryos; the first two volumes "will concentrate on consideration of peri-implantation embryogenesis and the maternal influences on the embryo".

Volume 1 contains an interesting mix of developmental biology and reproductive physiology, two disciplines that in the past, in spite of their obvious overlap, have had inadequate contact. Reproductive physiologists have concentrated on the female and the male, often forgetting that reproduction implies an embryo too; developmental biologists, because of their traditional pre-occupation with non-mammalian material, sometimes find it hard to come to grips with the endocrinological, physiological and anatomical complexities of the maternal–embryonic relationship in mammals. This volume should go far to bridge the gap.

The biochemical and biophysical aspects of pre-implantation development are comprehensively covered by T. Ducibella (surface changes and cell–cell interactions in trophectoderm), R. M. Borland (transport processes in the mammalian blastocyst, the trophectoderm as an epithelium), G. A. Schultz and E. B. Tucker (protein synthesis and gene expression) and C. M. Warner (RNA synthesis and RNA polymerase activity). On the reproductive side, J. E. O'Grady and S. C. Bell provide an exhaustive review of uterine aspects of implantation; M. A. H. Surani describes protein changes in uterine fluids at the time of implantation; R. J. Aitken deals with delay of implantation, and the signals that may switch embryo and uterus on and off; M. Beato discusses the synthesis of one particular uterine protein, uteroglobin. M. H. Kaufman reviews his work on the effects of anaesthetics on gametogenesis and post-implantation development, in the context of clinical studies.

It is sad that the only hint of the intellectual excitement of the field, and of the beauty and amazing ingenuity of the mammalian embryo, comes in the Editor's introduction. The articles themselves tend to get bogged down in experimental detail, often contradictory. One consequence of selecting authors who are themselves actively working in a rapidly moving area is that one gets up-to-the-minute information, much of it still unpublished; a less desirable consequence is that the viewpoint is inevitably one-sided. Some of the articles are definitive reviews of a topic (Aitken; O'Grady and Bell) but most are of the nature of progress reports. Such a collection requires stringent editing. Able research workers are not necessarily good writers; Dr Johnson fields an impressive team but allows them too much freedom.

Many linguistic errors and misprints mar the pages: I spotted 54 in one 80-page article, without picking any editorial nits over hyphens or punctuation. The heterogeneity of misprint-density suggests that proof-reading was left to individual authors. There are also infelicities such as "Neither results strongly support . . . "; all 'less than' signs are omitted from probability levels in one chapter; and why choose a typeface that distinguishes l from 1 if you then abbreviate chlorine as Cl throughout? The typed text is photographically reduced to a size that I (and others to whom I showed the book) found tiring to read.

These are minor criticisms. I wholeheartedly welcome the appearance of the new series, and congratulate publishers and Editor on their enterprise. I urge anyone with an interest in developmental biology or reproductive physiology to buy this volume, and to get their libraries to buy it too. It is worth the money for the comprehensive reference lists as well as for the articles themselves.

Anne McLaren is Director of the MRC Mammalian Development Unit at University College, London, UK.

Antinucleon physics

Antinucleon–Nucleon Interactions. Edited by G. Eskpong and S. Nilsson. Pp. xvii+600. (Pergamon: Oxford and New York, 1977.) £22.

THE ANTIPROTON was discovered in 1955 and the antineutron a year later, so antinucleons have only recently come of age. The interaction of these particles with nucleons is an active research field, and in the past few years has been the subject of a number of specialised symposia of which the latest was held in Stockholm in July 1976. These published proceedings of this meeting contain 8 invited review papers and about 50 research contributions. The discussion following each talk has not been recorded.

The existence of antiparticles suggests the intriguing possibility of bulk antimatter in the Universe. A cosmology symmetric between matter and antimatter has been championed for a number of years by H. Alfvén (Stockholm) who reviewed this topic. There is no evidence for galaxies or other distant regions of antimatter, but neither can their existence be ruled out from direct experimental measurements.

All other talks came down to Earth and covered aspects of antinucleon behaviour in the laboratory. The construction of separated antiproton beams of high intensity, in particular at the CERN and Brookhaven proton synchrotons, has greatly enhanced the scope of low and medium energy experiments in the last few years. Antiprotons transported at a few hundred MeV/c can be brought to rest in targets and used to study the $\bar{N}N$ system at very low energies. This topic was reviewed by T.E.O. Ericson (CERN). Theoretical models predict the existence of $\bar{N}N$ states bound by the strong nuclear interaction, but these have not been established definitely by experiment. Antiprotons can, however, certainly be bound to nuclei by the Coloumb force to form antiprotonic atoms. X-ray transitions between levels have been studied and a number of interesting results obtained including a measurement of the antiproton magnetic moment.

Formation experiments are a powerful technique for studying hadron resonances. At the appropriate centre of mass energy, the colliding particles coalesce briefly to create a single particle, which then decays. To study posible meson formation, a conventional nucleon target requires a beam of antibaryons, in practice antiprotons. A clear review by E. Eisenhandler (Queen Mary College, London) outlined the considerable recent progress in this field. A few years ago suggestive enhancements were seen at various mass values in the antiproton–nucleon total cross sections. More recently these bumps were seen also in the $\bar{p}p$ elastic channel. The investigation of other channels, in particular two-meson final states provides much additional information. Angular distributions for $\bar{p}p\rightarrow\pi^0\pi^0$; $\eta^0\eta^0$; $\pi^0\eta^0$ were presented by a Bari–Brown–MIT collaboration, and results for polarisation in $\bar{p}p\rightarrow\pi^+\pi^-$; $K^+ K^-$ by a QMC–Daresbury–Rutherford collaboration.

When the Fermilab accelerator started operation, antiprotons in the 100 GeV/c region were produced quite copiously. At these momenta, however, particle separation using electrostatic or even RF fields becomes prohibitively difficult. An ingenious scheme has been used where antiprotons arising from antilambda decay in a short neutral beam were then transmitted to the experiment. At 100 GeV/c, annihilations are reduced to perhaps only a tenth of all $\bar{N}N$ interactions. These annihilations were reviewed by J. G. Rushbrooke (Cambridge). Experiments are still exploratory, measuring multiplicities, topological cross sections and inclusive production spectra. Annihilations at medium energies, and related processes, were covered by J. R. Fry (Liverpool). High energy non-annihilation interactions, where baryon and antibaryon are still present in the final state, were reviewed by S. Nilsson (Stockholm).

Two invited theoretical reviews were given. H. Miettinen (SLAC) discussed progress in antiproton physics mostly within the framework of quarks and duality diagrams. Both he, and also G. F. Chew (Saclay and Berkeley) in a more speculative review, considered the possibility of 'baryonium' states which do not have the conventional quark–antiquark structure of mesons.

Some plans for future facilities were outlined in contributed papers, but unfortunately the symposium came a little too early to include recent ideas on antiproton beam cooling and the possibility of storing antiprotons and colliding them with protons, thus giving rise to collisions at superhigh energies.

The editors and publisher have produced an attractive volume which should be of considerable interest to specialists in the field. **P. I. P. Kalmus**

P. I. P. Kalmus is Reader in Experimental Physics at Queen Mary College, University of Londcn, UK.

Platelet research

Platelets in Biology and Pathology. Edited by J. L. Gordon. Pp. 388. (North-Holland: Amsterdam and New York, 1977.) $53.95; Dfl. 132.

THIS book is the first volume in a new series *Research Monographs in Cell and Tissue Physiology,* with J. T. Dingle as general Editor. This volume, written by recognised cognoscenti in the various areas of platelet research, may be considered as a collection of progress reports over the past decade's research, with emphasis on current work. J. L. Gordon is responsible for the excellent selective editing.

Few scientists, if any, working with platelets, can keep abreast of the progress in this very active and rapidly developing field. B. Maupins annotated bibliography on blood platelets, for example, contains about 1,300 references to work published in 1972. The authors of the present monograph have very effectively filtered the plethora of material and offer the reader a comprehensive survey of the present state of knowledge; they provide roughly 1,600 selected and useful references.

The book is divided into two parts. Part one comprises an outline of fundamental platelet reactions, part two deals with platelet constituents, cellular control mechanisms and their biological significance. The first chapter in part one, "Blood platelets as multifunctional cells" (J. L. Gordon and A. J. Milner) is a well written appetiser, very fitting to the contents of the book. I am convinced that scientists to whom platelet research may seem a somewhat restricted subject, will acquire by reading these pages an informed interest in the numerous biological phenomena in which platelets are involved. The remainder of part one deals with platelet adhesion and aggregation (Baumgartner and Muggli) and the platelet release reaction (MacIntyre).

The book's second part brings together a great deal of valuable information on the platelet plasma membrane (Jamieson and Smith), lipids (Deykin), filaments and microtubules (Crawford), various platelet receptors (Mills and Macfarlane), biogenic amines (Drummond), platelets and thrombin (Majerus *et al.*), connective tissue and platelets (Jaffe), β-thromboglobulin (Moore and Pepper), platelets in immunological reactions (Brown), prostaglandins (Smith and Silver), platelet proteinases (Ehrlich and Gordon) and platelet growth-stimulating factor (Ross *et al.*).

In general, the chapters are well balanced; they bring out points of significance and offer a great deal more than a mere catalogue of original sources of information. It is to be hoped that some of the messages of the book will be widely appreciated—namely, that we still know next to nothing about the physiological importance of the many *in vitro* platelet phenomena so eagerly studied at present; that enough information has accumulated on interspecies differences in platelet chemistry and behaviour to make generalisations difficult or impossible; and that animal models for the study of the pathogenesis of human pathological conditions involving platelets are therefore very difficult to establish.

I found this monograph stimulating and I recommend it to anyone wishing to acquire an overall impression of the major developments and current lines of thought in the platelet field.

O. Behnke

O. Behnke is Professor at the Institute of Anatomy, University of Copenhagen, Denmark.

Parasitic protozoa

Parasitic Protozoa. Vol. 1: Taxonomy, Kinetoplastids and Flagellates of Fish. Edited by Julius P. Kreier. Pp. xv+441. (Academic: New York and London, 1977.) $35; £24.85.

THIS volume is the first of a series of four which are planned to present, in all, 40 chapters written individually by experts in each particular field and covering mainly the parasitic Protozoa but including also a number of organisms which are not, or only doubtfully, Protozoa, such as *Anaplasma, Eperythrozoon* and *Pneumocystis.* This is not so incongruous as might appear at first sight, as these organisms resemble the Protozoa in multiplying in their vertebrate host. The scope is, in fact, a welcome change from the more usual association of the Protozoa with only the helminths under the blanket term 'parasitology'.

The present volume contains 10 reviews, rather variable in length from about 25 to about 75 pages. The first two deal with taxonomy—respectively, with the position of the phylum Protozoa in the Animal Kingdom and with the internal classification of the phylum. The remainder deal exclusively, or predominantly with kinetoplastid flagellates and are rather variously defined. There are two defined purely taxonomically—the reviews of *Leishmania* and *Trypanosoma cruzi. Trypanosoma* is otherwise treated in six reviews defined by pathogenicity in relation to host and to geographical distribution—those species causing diseasesin man and other primates, or in cattle in subsaharan Africa or elsewhere, and those species generally regarded as 'non-pathogenic'. Finally, there is a treatment of the flagellate parasites of fish in which kinetoplastids figure largely but which also include dinoflagellates and polymastigids.

All the reviews are very readable, comprehensive and accurate treatments and (assuming their scope) are excellent summaries of the present states of knowledge for each field. Within the space provided for each review it is not possible to go into much discussion of matters which are still controversial, and so some statements will inevitably seem dogmatic on wider reading. Nevertheless, the reviews are all excellent lead-ins to their subjects and will be very useful for students and for research workers. The book is well produced, referenced and indexed. Its cost, nearly £25, seems high, even in these times, as it is only rather sparsely illustrated with a few line drawings and photographs. **W. H. R. Lumsden**

W. H. R. Lumsden is Professor and Head of the Department of Medical Protozoology at the London School of Hygiene and Tropical Medicine, London, UK.

Vertebrate evolution

Problems in Vertebrate Evolution. Edited by S. Mahala Andrews, R. S. Miles and A. D. Walker. Pp. xi+411. (Academic: London and New York, 1977.) £18.50; $36.10.

THIS volume of thirteen papers by vertebrate palaeontologists is a mark of their respect and regard for Professor Stanley Westoll on the occasion of his retirement. The subjects covered are, like his own interests, centred on fishes but extend also into the functional anatomy of tetrapods.

The commonest theme is the problem of comparative anatomy, in the sense of the search for the methods of establishing homology between structures in different groups, and also the application of these methods. Schaeffer develops the interesting and basic hypothesis that the dermal skeleton is always the result of an interaction between the epithelium and the underlying mesenchyme, and that its different manifestations (as enameloid, enamel, dentine or membrane bone) are merely the results of changes in the timing, duration or number of steps in the series of morphogenetic events. In another important paper, Patterson concludes that, contrary to current belief, there is no interchangeability between membrane bones and cartilage bones (though the two may fuse together), and that superficial "dermal" bones must be distinguished from membrane bones, the latter ossifying deep in the mesoderm. Ørvig gives a comparative survey of the superficial dermal structures, toothlike in appearance though not in position or function, that he calls odontodes. Gardiner and Bertram discuss the braincases of two new palaeoniscids and conclude that the ventral cranial fissure represents the gap between the ossifications in the trabecular–polar bar and the basal plate. Thomson discusses the ontogeny of cosmine, and suggests that the pore-canal system of Palaeozoic fishes had an electroreceptive function. Finally, Whiting returns to the problem of the identification of the cranial nerves of cephalaspid fishes, and provides considerable evidence that Stensiö's numbering of these should be revised.

The often bewildering interplay between ontogeny, functional anatomy and phylogeny is well shown by Panchen's work on the variety of vertebral structure in early tetrapods, and by Mahala Andrews' paper on the implications of some new features in the axial skeleton of *Latimeria*—since we still know virtually nothing of it as a living creature, its frequent mention as a "living fossil" in popular articles is rather ironic! On a related topic, Parrington suggests that intercentra were retained in the neck of cynodonts to increase the flexibility of this region. Finally, Walker provides some new ideas on the vexed question of the relationships between the functional morphology of the pelvic girdles of birds and dinosaurs (and, by implication, the relationships of their owners).

There are three papers primarily concerned with systematic work. Miles and Young describe new ptyctodontid placoderms from Australia, and provide arguments for a new classification of placoderms in which the arthrodires (*sensu stricto*) and antiarchs are closely related to one another. Jarvik finds a surprising degree of similarity between the detailed cranial anatomy of *Acanthodes* and that of living sharks, and suggests that these two groups are far more closely related than had been thought. Finally, Carroll explores the implications of his recent work on the earliest known (Permo–Triassic) lizards, discussing the basic adaptive pattern and early evolution of the group; he also suggests that sphenodontids are more closely related to the lizards than to the rhynchosaurs.

The volume has an attractive format and a good index. None of the papers in it are trivial, most are well-written (though occasionally blemished by imperfect proof-reading), and the volume deserves a place on the bookshelf of anyone working on the comparative anatomy and evolution of fishes.

Barry Cox

Barry Cox is Professor of Zoology at King's College, University of London, UK.

Ultraviolet photoelectron spectroscopy

Principles of Ultraviolet Photoelectron Spectroscopy. By J. Wayne Rabalais. Pp. xv+454. (Wiley Interscience: New York and London, 1977.) $36; £22.50.

THIS is really a very good book which will be useful to photoelectron spectroscopists for many years to some—no mean achievement in such a rapidly changing research field. The author has not fallen into the trap of undue concentration on spectra of specific molecules or indeed of paying special attention to particular research areas within the ultraviolet photoelectron spectroscopy (PES) field. Rather, there has been a deliberate policy of concentrating on the fundamental principles of the various effects which are encountered in PES and for once the book's title is a true reflection of the content. In my opinion, the author was also correct in concentrating on the vacuum ultraviolet aspects of photoionisation electron spectroscopy, a subject which provides direct information on the eletcronic structure of molecular ions, rather than diluting the contents in an attempted comprehensive electron spectroscopy text.

The detailed content of the book is significantly different from that found in existing texts, and the degree of overlap is remarkably low. A suitably short introduction is followed by a brief but adequate chapter on experimental methods. Chapter three is a useful one in that it brings together, in a mathematical way, a number of related topics such as photoionisation, Franck–Condon factors, isotope effects, selection rules and configuration interaction. The next chapter deals with the theoretical methods used to describe and quantify ionisation from closed-shell molecules. This chapter is adequate, although a colleague thought that a discussion of the more recent molecular orbital methods such as the *ab initio* many body approach, the equations of motion method and the application of time-independent perturbation theory to the problem of calculating ionisation energies could have been included to advantage.

The next three chapters are ones which are not standard content in books on PES and for this reason are especially useful to researchers in the field. Chapter five deals with the special aspects of ionisation from open-shell molecules in a mathematical fashion, and includes a good account of the vector-coupling method for open shells. Chapter six deals with the theory of photoionisation cross-sections in as reasonable a way as is at present possible, since considerable development work is still required in this area. The following chapter deals with the interpretation of photoionisation cross-sections and angular distributions within the limits of our present day understanding.

Chapter eight is a detailed account of spin-orbit coupling in molecular ions and chapter nine is concerned with configurational instability of molecular ions—basically, the Jahn–Teller and Renner effects. On balance, the topics in chapter nine are discussed in rather more detail than one might justify from their importance in experimental PES. The last two chapters are more conventional and are basically concerned with experimental results and their interpretation.

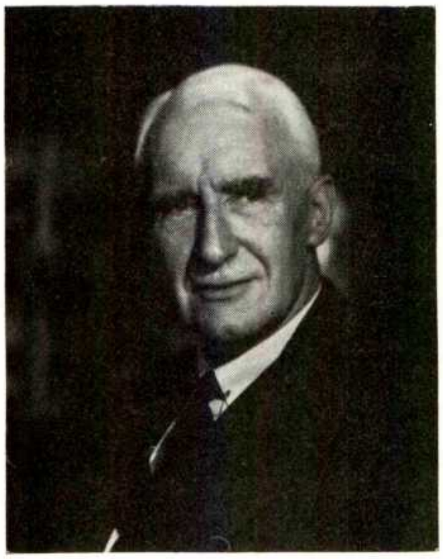
obituary

A. V. Hill

A. V. Hill died at his home in Cambridge on 3 June, in his 91st year. A.V., as he was known to his colleagues all over the world, was one of the great scientific leaders of his generation. He will be remembered not only for his pioneering work on the energy exchanges in active nerve and muscle, but for bringing physico-chemical ideas and precision measurements to bear on biological problems, and above all for his personal example and influence in inspiring and encouraging many of his younger colleagues, and in helping those who had been driven from their laboratories by political or racial persecution.

He was born at Bristol on 26 September 1886, went to Blundell's School at Tiverton, and in later years maintained a close connection with the West Country. He used to spend many summer months in Devonshire, staying with his family at 'Three Corners', his little house in Ivybridge, and working from time to time at the nearby Marine Biological Laboratory at Plymouth. In 1913, A.V. married Margaret Keynes, sister of John Maynard and Geoffrey Keynes, starting a partnership which lasted for nearly 60 years, and a pleasant family home whose hospitality is remembered by colleagues and friends from many countries.

At Blundell's School, he was profoundly influenced by J. Thornton, an outstanding mathematics teacher who also taught his pupils the need for clarity in thought and precision in the use of words. In 1905, A.V. went to Trinity College, Cambridge as a Scholar, taking mathematics and finishing as 3rd Wrangler in 1907. Under the tutelage of W. M. Fletcher (later the first Secretary of the Medical Research Council), he decided to turn to physiology and in 1909 took a first in part II of the Natural Sciences Tripos. The year after, he was made a Fellow of Trinity College.



In the Physiological Laboratory at Cambridge, A.V. found himself in the company of outstanding people, among them Joseph Barcroft, Keith Lucas, J. N. Langley, Walter Fletcher and F. Gowland Hopkins. He started by publishing theoretical papers on nerve excitation and on the kinetics of the oxygen-haemoglobin reaction. The latter is still referred to on occasions, when authors use the so-called 'Hill-coefficient' as a characteristic index in aggregate or cooperative molecular interactions. But before long, A.V. embarked on his own experimental research which he pursued, with interruptions caused by two world wars, for the next 55 years.

He followed Langley's advice to investigate 'the efficiency of the cut-out frog's muscle as a thermodynamic machine.' This became an unending story, in which he was helped by his assistants A. C. Downing and J. L. Parkinson, developing instruments of increasing sensitivity, greater time resolution and better stability, a story of continuously searching for errors in technique and interpretation, of replacing obsolete results and ideas with better experiments and fresh hypotheses; it was a process of temporary setbacks and continuously improved experimentation that gave A.V. the greatest pleasure and provided him with the kind of entertainment he enjoyed throughout his life. His early measurements of heat production in active muscle, analysing and dividing it into an initial anaerobic, and a subsequent, oxygen-requiring recovery phase, correlating them with what was known about lactic acid production and oxidative restoration processes, is now part of classical history, but at the time it was a most exciting technical and experimental advance and represented one of the outstanding contributions to our knowledge. Moreover, A.V. was quick in extending the work and applying it to the study of muscular exercise and the associated oxygen requirements in man.

Hill's preoccupation with precise and exceedingly sensitive myothermic measurements had some important 'spin-off.' It enabled him to detect the heat production during the conduction of nerve impulses, a feat which many distinguished scientists, among them the great Helmholtz, had attempted, but failed to bring off. In addition, A.V. showed that his thermopiles could be applied to practical problems, in measuring osmotic pressure of very small volumes of body fluids, and in determining arterial elasticity and pulse wave velocity. Although he once publicly admitted that he did his work 'not because it is useful, but because it's amusing', he was nevertheless accustomed to looking at living machinery with the eyes of a practical engineer. This, together with his personal interest in athletics, prompted him to study muscular movement not only in isolated frog muscles, but in man, and to work out the relations between physical dimensions of different animals and the limits to the speed and power of their muscular performance.

Hill's early work in the Cambridge laboratory came to a halt in 1914; he joined the Cambridgeshire Regiment, served as Captain and Brevet Major and later became Director of the Anti-Aircraft Experimental Section, another useful outlet for his engineering interests. He recommenced his muscle experiments in Cambridge at the end of the war, but in 1920 went to the Physiology Chair in Manchester. Three years later, he moved to University College London, first as Jodrell Professor of Physiology, then as Foulerton Professor of the Royal Society. He stayed at UCL, working in the laboratory for many years after his official retirement, until 1967 when he returned to Cambridge, leaving behind a Biophysics Department which he had founded in 1951.

A. V. Hill gave public service of many different kinds. During the uneasy years before 1939, he joined the Tizard Committee which initiated radar defence, and he also accepted the task of compiling a Central Register of Scientific and Technical Personnel in anticipation of wartime needs. He did this during a period when he was fully engaged in his laboratory, working single-handed on new experiments which resulted in the publication of one of his most important papers, on the energy liberation and the heat produced during shortening of active muscle. At the same time, he served as Biological Secretary of the Royal Society and on numerous scientific committees, and took a leading part in helping refugee scientists.

During the 1939/45 war he was Member of Parliament for Cambridge University, and he served as Scientific Adviser to the Government of India in 1943-44. To name only some of his other extramural activities, he served the Physiological Society, on its Committee, and as an Officer and Editor of its Journal, for 25 years, was Foreign Secretary of the Royal Society, Secretary General of the International Council of Scientific Unions, President of the British Association in 1952 when he gave his memorable address on 'The Ethical Dilemma of Science', and Chairman of the Society for the Protection of Science and Learning. A.V. gave a powerful stimulus to the study of marine biology in this country. He was President of the Marine Biological Association, and he constantly encouraged his younger colleagues to work at Plymouth and take advantage, not only of its delightful surroundings, but of the unique opportunities for experiments provided by the marine fauna. This initiative, together with his fascinating Liversidge Lecture on 'Chemical Wave Transmission in Nerve' helped to attract a number of distinguished biologists to the Plymouth Laboratory which later on led to very striking developments in the neurophysiological field.

A.V. was honoured by academic institutions all over the world; he was made a Companion of Honour in 1946 and received high honours from the Governments of France and the United States. At the age of 31 he was elected to the Royal Society who later awarded him the Royal and Copley Medals, and he received the 1922 Nobel Prize for Physiology together with Otto Meyerhof.

He is remembered and held in affection by all his pupils, not only as a great scientist who imparted to them the joy and spirit of adventure in doing experiments, but as a man who gave an example of uncompomisingly straight dealing, in the laboratory as well as outside. The pursuit of truth was to him not simply a scientific exercise, confined to one's work in the laboratory and presentation of results; it also governed his attitude in all his actions and in his relations to other persons. He was unrelentingly critical and never ceased to probe for flaws in his own deductions or experimental approach. 'To be uncritical', he said, 'particularly of oneself and one's ideas and motives, is the first long step towards dishonesty.' Yet, he never permitted his intellectual austerity to damp his enthusiasm, and I do not believe he ever allowed the slightest doubt to arise in his mind about the importance of the work he was engaged in. This buoyancy transmitted itself to those who were associated with him and helped to carry them over periods of failure and possible frustration. A.V. liked to get a good laugh out of situations which others might have regarded as perhaps slightly embarrassing; he detected and managed to focus on the humorous side of people's failings including his own. He retained, until nearly the end, a delightful, boyish sense of humour which greatly appealed to most of his friends, though at times it may have puzzled the more serious-minded ones among them.

I shall always remember a particular occasion in 1934. I was then a medical student in Leipzig, about to take my finals and anxiously making plans to escape from a hostile environment. I came across a correspondence in *Nature* between A. V. Hill and Johannes Stark, a famous physicist who had become the scientific 'Gauleiter' in Nazi Germany. After the 1914–18 war, A.V. had insisted (against some initial resistance) that colleagues from Germany should be invited straight away to attended International Congresses and be made to feel welcome in the scientific community. But in 1933 he was also the first to speak out vigorously against the Hitler regime and the dismissal and persecution of Jewish scientists. He was promptly taken to task by Professor Stark who stated in two letters to *Nature* that there was no factual basis for A.V.'s critical remarks, that the Nazi Government was obliged in self-protection to restrict the influence of certain persons and was simply engaged in lawful activities like any other respectable Government. The correspondence ended with a short note from A.V. in which he said that monetary contributions had been received in response to his appeal for assistance to colleagues who had been driven out of Germany. He added that he was not quite certain whether the donations were the result of his own eloquence, or rather of the explanations given by Professor Stark to whom, he felt some thanks were due. The *Nature* correspondence gave me my first impression, from a distance, of A.V.'s personality, and I found it so attractive that I made every effort to go and work with him as soon as I could.

There will be hundreds of scientists from different continents who recall with gratitude the welcome and hospitality they received, not only in the laboratory in Gower Street, but from A.V. and Margaret at their home in Highgate and at 'Three Corners' in Devonshire. Last year, on his 90th birthday, well over a hundred of his friends sent him a large volume containing greetings and reminiscences, and A.V. very much enjoyed browsing through them during the remaining months of his life. There can be few scientists and teachers who have won as much affection as A.V., and I believe that his personal influence among his scientific descendants in all parts of the world is a contribution to international scientific relations, not on a large scale, but of a kind perhaps more valuable than anything that official organisations could provide.

B. Katz

Roman Kozlowski

PROFESSOR ROMAN KOZLOWSKI, who died on 2 May, 1977, at the age of 88, was perhaps the most internationally honoured doyen of invertebrate palaeozoology. He was responsible for establishing a school of palaeontological study at Warsaw of exceptional breadth and excellence. His major contributions were on the Brachiopoda and Graptolithina, but he made some contributions on most other invertebrate fossil groups.

He was born on 2 February, 1889, at Wloclawek, north-west of Warsaw, Poland, and in 1907 he attended the University of Freiburg, and continued his geological and biological studies at the Sorbonne where he graduated in 1910. Between 1913 and 1921 Kozlowski was Professor of Geology and Mineralogy and later Director of the School of Mines at Oruro, Bolivia. It was during this period that his early work on the Carboniferous Brachiopoda and Devonian faunas of Bolivia was mostly done. The latter field he developed for a doctoral thesis under Professor Marcellin Boule (whom he affectionately spoke of as 'mon Maitre') which he received in 1923: the monograph, published in the *Annales de Paléontologie*, set a new standard for palaeontological illustration by collotype.

In 1924 he returned to Poland to teach at the University of Warsaw, becoming a full Professor of Geology and Palaeontology in 1934 and Chairman of the Palaeontology Department. Then really began the progressive growth to excellence of his department. His first major subsequent work followed visits in 1925 and 1926 to the Dneiper River sections in Podolia. The resulting monograph *Les brachiopodes gotlandien de la Podolie polonaise*, has been described by Shirley as 'a source of inspiration for a generation'; but this referred to the impeccable standard set by his brachiopod descriptions, especially of their internal structures. It was seminal in another way, since it gave details of a marine sequence passing from the Silurian into the Devonian. The area has recently been critical for the international definition of the Silurian/Devonian boundary.

In 1931 he noticed that graptolites were preserved in translucent chalcedony in Tremadocian rocks of the Holy Cross Mountains, and he discovered how easily these could be extracted by dissolution in hydrofluoric acid. This led eventually to the discovery of three new groups of graptoloid, and the discovery of much new detail on the ontogeny of the dendroid graptolites, and also the development of immaculate serial sectioning techniques. It also led to the extension of the techniques to other periods and a corresponding range of contributions on other groups.

The story of the survival of Kozlowski's manuscript for his monograph on Polish Tremadocian graptoloids is a most harrowing tale. His work was completed in 1939 and the bombing of Warsaw imperilled his laboratory, so he moved the typescript, illustrations and most of the specimens to a basement below the Seismological Conservatoire: his institute was destroyed. The Conservatoire was also destoyed, but a month later he was able to enter the basement, but found it sacked, and his material missing. Several months later he found part of his original manuscript in the university ruins, and shortly after, his friend Dr Rozkowski, who was later assassinated, discovered the remainder buried under snow in a courtyard.

At the Warsaw uprising of August 1944 Kozlowski was expelled, but first he hid his manuscript in the central heating system of a private house and, although the house was ruined, he was able to rescue the manuscript in 1945. The originals for his plates were lost, but since he had taken the precaution of sending negatives of these to Paris in 1939, he was able to publish the monograph in 1949. Immediately, this establshed a new reputation for him in the field of the graptoloids. Particularly important was the detailed case he argued for assigning this important fossil group to the Pterobranchia of the Hemichordata.

After the Second World War he returned to teaching and built up his research school again and until 1960, when he retired, he was Chairman of the Palaeontological Institute of the Polish Academy of Sciences in Warsaw. When the writer visited him in 1962 he was enthusiastically engaged in preparations for the Polish Mongolian expeditions which have led to so many valuable studies under the direction of his former student Professor Kielan-Jaworowska.

The Geological Society of London awarded him the Wollaston Medal in 1961; he was an honorary member of many Polish and international scientific societies, an honorary graduand of the universities of Krakow, Paris and Modena, a member of the Academies of Science of Poland, Czechoslovakia, France and Colombia; he was a Polish Scientific Prize-winner of the first degree.

The most important other monuments to the work of Roman Kozlowski are the two periodicals which he founded, namely, *Palaeontologica Polonica* of which he edited thirty-four volumes between 1929 and 1976, and *Acta Palaeontologica Polonica* which he edited from 1956 to 1974. These record the incredible breadth of research work done largely by himself and his students and research associates, and give an indication of his infectious enthusiasm for all branches of palaeobiology.

Michael House

George Cotzias

On June 13, 1977, just 3 days before his 59th birthday George Cotzias died of lung cancer. With his untimely passing the world lost a prominent neurobiological investigator who had made a number of fundamental contributions to the field.

Born in Athens, Greece, the son of a prominent political figure, he fled to the United States in 1941 when his country was occupied during World War II. His medical education which had begun at the University of Athens was continued at Harvard where in 1943 he was awarded the MD degree. Dr Cotzias then served as a house physician on the neurological and medical services of the Massachusetts General Hospital following which he began his career in research at the Rockefeller Institute in New York City. His initial interest centred on renal function but he soon became intrigued with the biological role of trace metals in tissue metabolism particularly in regard to the nervous system.

I remember well my first contact with Dr Cotzias in the 1950s. He was working on the mechanisms by which enzymes involved in oxidative phosphorylation were activated by manganese and how this might alter central nervous system function. I was organising a symposium on parkinsonism and invited him to discuss his work. Over a three-day period in the Ramapo Mountains of New York I came to know George's innovative and individualistic approach to science; his keen mind, his wit and gregarious yet unimposing nature.

He was then working at the Brookhaven National Laboratories to which he had moved in 1953 and where laboratory and clinical facilities were made available to him. Gathering a substantial team of investigators around him he began expanding his investigative program with particular interest in the biochemical mechanism underlying extrapyramidal and behavioural disorders. Stimulated by his previous work with manganese, as well as the growing body of information concerning the possible role of monoamines in melanin pigment formation, he was deeply involved in defining its role in Parkinson's disease. Though many were exploring the therapeutic value of monoamines particularly dopa in the treatment of parkinsonism, none approached it with the tenacity and courage of George Cotzias. Where others were constrained by adhering to the usual principles of therapeutics, he felt that the brain mechanisms were unique and required a more adventurous approach. The dramatic effects of reversing the symptoms of parkinsonism by giving large doses of L-dopa which were achieved by the Cotzias's group is undoubtedly one of the major milestones in the treatment of neurological disorders. Not only have literally millions with the disease benefited from its use, but the therapeutic principle has found applicability to other disorders. Despite being hailed by some as a panacea for Parkinsonism, Cotzias was the first to admit that it offered only a prolonged holiday from the symptoms and much more had to be done to effect a cure. Indeed, he devoted the last 10 years of his life to looking for more effective means of overcoming the dopamine deficiency in the brain of parkinsonians.

Dr Cotzias received many honours during his life, among which were the Albert Lasker Award in Clinical Medical Research in 1969, the Borden Award in 1972 and the Oscar B. Hunter Award from the American Society of Clinical Pharmacology and Therapeutics in 1973. His native country recognised his contributions with an Honorary Doctor of Medicine degree from the National and Kapodistrian University in Athens, and in appointing him Grand Commander of the Royal Greek Order of the Phoenix and the Archon Actuarius of the Ecumenical Orthodox Patriarchate.

At the time of his death he was Professor of Neurology at the Cornell Medical College, Attending Physician at New York Hospital and a Special Assistant to the President of the Memorial Sloan-Kettering Cancer Center. He had accepted these positions in 1974, moving his laboratories and personnel just prior to becoming ill. Despite this, he continued to be active and involved in a number of new fields of investigation related to the aging process in the nervous system and mechanisms involved in carcinogenesis. Undoubtedly, this work will be carried forward by his colleagues and collaborators, many trained by him over the years. Yet his presence will be sorely missed in the scientific community throughout the world.

Melvin D. Yahr

C. F. Hickling

Dr C. F. Hickling, CMG, ScD, who died on 14 June at the age of 74 had a unique influence on the development of marine, lake and river fisheries and fish culture over the wide extent of the former British Empire. He was educated at Taunton School and then at St. Catherine's College, Cambridge, to join, in 1927, the staff of the Fisheries Laboratory at Lowestoft. He was a born fisheries naturalist, as keenly interested in the methods of fishing and in the fishermen as in collecting data and interpreting their significance. His prime concern was with the hake fishery, to rise and then fall during this period. It has rightly been said that our knowledge of the biology of that fish owes everything to him. This formed the subject matter of a series of reports largely summarised in his Buckland lectures for 1934 on *The Hake and the Hake Fishery*.

During the war he was Port Fishery Officer at Milford Haven. In 1945 he was appointed Fisheries Adviser to the Secretary of State for the Colonies. In 1961, a year before his retirement, he was transfered to the Department of Technical Co-operation. His activities were literally world-wide, on innumerable islands in the Caribbean and Pacific, in East and West Africa, in Malaya, Singapore, Hong Kong and Sarawak. He advised on river fisheries in Nigeria, on those of the great lakes of Central Africa—then on those of the created Lake Kariba—and promoted development of sea fisheries off African and Pacific coasts.

He was responsible for the organisation of training courses for fisheries officers appointed during this belated period of colonial activity, also for advice on the location and planning of research laboratories notably at Entebbe in Uganda, in Zanzibar, on Lake Nyasa, at Freetown, Sierre Leone and at Singapore. The largest scheme, carried through during the communist troubles, was the Tropical Fish Culture Institute at Malacca of which, there happily accompanied by his wife, Marjory, he was Acting Director in 1957-59. There he succeeded in crossing strains of *Tilapia mossambica* to produce unisex cultures which grew without the runting that accompanies the early reproductive activities in these fish.

It was a notable experience, as the writer can testify, to accompany Fred on a tour. He moved from the Governor's residence to the humblest fish landing, advising on scientific and commercial policy and then on the fitting of outboard motors to dug-out canoes, on the quality and handling of nets and on preserving and marketing of the catch. He was rightly described as a 'one man FAO'.

He leaves much of his wide knowledge to posterity in the pages of his books on *Tropical Inland Fisheries* and *Fish Culture*. All who knew him remember him with deep affection, so utterly the right man in the right place. We think also of his widow and two sons.

Maurice Yonge

J. A. Robbie

James Andrew Robbie, FRSE, FGS, died in Edinburgh in his 67th year on 19 May 1977. Born near Laurencekirk he graduated BSc with Honours in Geology at Aberdeen University in 1934. After a short period as Demonstrator in the Geology Department there he was appointed Geologist in the Geological Survey of Great Britain in 1935. He served initially in southern England carrying out geological surveys in the vicinity of Chatham, Bridport and Yeovil. Publication of his work was delayed by the Second World War but eventually appeared as a paper on the Chalk Rock at Winterborne Abbas in his favourite county of Dorset and contributions to the Geological Survey Memoirs on Chatham and Bridport and Yeovil. Although concerned with water supply, mineral resources and airfield construction during the war he was located in London, a period of his life which evoked vivid tales of the blitz and food shortages, the latter being the greater burden for the gourmet.

In 1947 he was transferred to Belfast as part of the team which initiated the Geological Survey of Northern Ireland. On promotion to District Geologist in charge of the Belfast Office in 1959 he was instrumental in establishing the close relationships with central and local government which have resulted in a key role for the Geological Survey in the area. The acme of his geological career came in Northern Ireland with many studies including those of the Mourne Mountain granite as revealed in the Slieve Binnian Tunnel and of the Carboniferous stratigraphy proved by boreholes between Coalisland and Dungannon, published in the Bulletin of the Geological Survey of Great Britain. The scope of his experience and knowledge is demonstrated by his accounts of lithology, stratigraphy and structure of strata of the Dalradian, Silurian, Carboniferous, Triassic, Rhaetic, Liassic, Cretaceous, Tertiary and Pleistocene in memoirs describing the geology of the Dungannon, Ballycastle and Belfast districts.

When promoted to Edinburgh to be Assistant Director in charge of all the activities of the Institute of Geological Sciences in Scotland he was so deeply entrenched in Northern Ireland geology that his model became something of an anathema to the Scots in their analyses of local geology. While involved in the expansion of IGS activities both on land and offshore he played a major role in planning and developing Murchison House, the new headquarters of IGS in Scotland, which was nearing completion as he retired in 1975.

Elected a Fellow of the Royal Society of Edinburgh in 1968 he was appointed Vice President in 1975. He was a Fellow of the Geological Society of London, served as President of the Edinburgh Geological Society from 1971–73, and was elected an Honorary Member of the Belfast Geologists' Society of which he was President twice. In his official capacity he served on the Council of Management of the Macaulay Institute for Soil Research from 1969 until 1975.

A quiet, shy, self-effacing man Jim Robbie shunned the social scene and yet enjoyed nothing more than to meet friends over a glass of his favourite national spirit. He faced his retirement full of plans for remodelling his garden, refurbishing his beloved old car and travelling the world, plans only in the earliest stages of fulfillment when he died.

Recent scientific and technical books

Mathematics

BECK, Robert E., and KOLMAN, Bernard (edited by). Computers in Nonassociate Rings and Algebras. Pp.ix+297. ISBN-0-12-083850-8. (New York and London: Academic Press, a Subsidiary of Harcourt Brace Jovanovich, Publishers, 977.) $14; £9.95.

BENEDEK, Pal. SIMUL—Eir Programm für die Mathematische Simulation von Verfahrenstechnischen Systemen. Pp.328. ISBN-963-05-1111-8. (Budapest: Akadémiai Kiadó, 1977.) £10.50.

HINTON, E., and OWEN, D. R. J. Finite Element Programming. (Computa-onal Mathematics and Applications.) Pp.xii+305. ISBN-0-12-349350-1. (London nd New York: Academic Press, a Subsidiary of Harcourt Brace Jovanovich, ublishers, 1977.) £11.80; $23.

GIRI, Narayan C. Multivariate Statistical Inference. (Probability and Mathe-atical Statistics: a Series of Monographs and Textbooks.) Pp.xvi+319. ISBN-0-2-285650-3. (New York and London: Academic Press, a Subsidiary of Harcourt race Jovanovich, Publishers, 1977.) $25; £17.75.

MANDELBROT, Benoit B. Fractals: Form, Chance, and Dimension. Pp.xvi+65. ISBN-0-7167-0473-0. (San Francisco: W. H. Freeman and Company, 1977.) 14.95.

SYMPOSIA MATHEMATICS, Vol. XX. (Ostituto Nazionale di Alta Matematica.) Pp.576. (Roma: Istituto Nazionale di Alta Matematics, 1976. Distributed hroughout the world by Academic Press, London and New York.) £17.70; $34.50.

WALLACE, Andrew. Differential Topology: First Steps. (Mathematics Mono-raph Series.) Pp.xi+130. ISBN-0-8053-9485-0. (Reading, Mass. and London: W. A. Benjamin, Inc., 1968. Second printing (with corrections), 1977.) $7.50.

Astronomy

GRIBBIN, John. White Holes: Cosmic Gushers In The Universe. Pp.200+23 photographs. (St. Albans, Herts: Paladin, 1977.) £1.50.

KOLCHINSKII, I. G., KORSUN, A. A., and RODRIGES, M. G. Biografi-cheskii Spravochnik (Astronomers—Biographical Directory.) Pp. 415. (In Russian). (Kiev: Naukova Dumka, 1977.) 1 ruble 65 kopeks.

KUCHOWICZ, B. Nuclear and Relativistic Astrophysics and Nuclidic Cosmo-chemistry: 1963-1967, Vol. 1. Pp.xiv+366. ISBN-0-677-02760-5. (New York, London and Paris: Gordon and Breach, Science Publishers, 1976.) £24.70.

RUKL, Antonin. Moon, Mars and Venus: a Concise Guide in Colour. Pp.255. SBN-0-600-36219-1. (London, New York, Sydney and Toronto: Hamlyn, 1976.) 1.50.

SINGH, Jagjit. Great Ideas and Theories of Modern Cosmology. Revised and nlarged edition. Pp.416. ISBN-0-486-20925-3. (New York: Dover Publications, nc.; London: Constable and Co., Ltd., 1977. First published 1961.) £3.20.

Physics

BARANGER, Michael, and VOGT, Erich (edited by). Advances in Nuclear Physics, Vol. 9. Pp.xiv+264. ISBN-0-306-39109-0. (New York and London: Plenum Press, 1977.) $29.40.

BARBOUR, I. M., and DAVIES, A. T. (edited by). Fundamentals of Quark Models. (Proceedings of the Seventeenth Scottish Universities Summer School in hysics, St. Andrews, August 1976. A NATO, Advanced Study Institute.) Pp.588. SBN-0-905945-00-X. (St. Andrews: Scottish Universities Summer School in ysics, 1977. Obtainable from SUSSP Publications, Edinburgh University Physics epartment, King's Buildings, Mayfield Road.) £12.

BUSCH, Georg, and SCHADE, Horst. Lectures on Solid State Physics. Trans-ed by Ferdinand Cap. Translation edited by D. ter Haar. (International Series in tural Philosophy, Vol. 79.) Pp.xv+538. ISBN-0-08-016894-9. (Oxford and New rk: Pergamon Press, 1976.) £10.

CRANGLE, J. The Magnetic Properties of Solids. (The Structures and Properties Solids, 6.) Pp.xiii+194. ISBN-0-7131-2574-8. (London: Edward Arnold (Pub-hers), Ltd., 1977.) Board £10; Paper £4.95.

EISENBERG, A., and KING, M. Ion-Containing Polymers: Physical Properties and Structure. (Polymer Physics, Vol. 2.) Pp.xvi+287. ISBN-0-12-235050-2. (New York and London: Academic Press, a Subsidiary of Harcourt Brace Jovanovich, Publishers, 1977.) $27.50; £19,55.

HASKELL, P. H. (edited by). The Structure of Non-Crystalline Materials. roceedings of the Symposium held in Cambridge, England on 20-23 September 76. A *Physics and Chemistry of Glasses* Conference Volume.) Pp.262. ISBN-0-066-120-X. (London: Taylor and Francis, Ltd., 1977. Published on behalf of e Society of Glass Technology.) £15 net.

KLEIN, M. L., and VENABLES, J. A. (edited by). Rare Gas Solids, Vol. 2. xi+609-1252. ISBN-0-12-413502-1. (London and New York: Academic Press, ubsidiary of Harcourt Brace Jovanovich, Publishers, 1977.) £26; $50.75.

NIKOLIC, M. (edited by). Methods in Subnuclear Physics. (Proceedings of the rnational School of Elementary Particle Physics, Herceg-Novi, Yugoslavia.) V, Part 1: Pp.vi+496. ISBN-0-677-15910-2.Vol. V. Part 2: Pp.vi+364. ISBN 7-1590-X. (New York, Paris and London: Gordon and Breach Science Publishers, .) £42.90.

ARISH, Leonard. The Logical Flaws of Einstein's Relativity. Pp.vii+171. N-0-904378-03-9. (Luton: Cortney Publications, Windmill Road, 1977.) £6.50.

ETERKOP, R. K. Theory of Ionization of Atoms by Electron Impact. Trans-on edited by D. G. Hummer. Pp.vi+263. ISBN-0-87081-105-3. (Boulder: lorado Associated University Press, 1977.) $10.95.

VIJH, Ashok K. (edited by). Oxides and Oxide Films. (The Anodic Behavior of tals and Semiconductors Series, Vol. 5.) Pp.xi+184. ISBN-0-8247-6580-X. (New ork and Basel: Marcel Dekker, Inc., 1977.) SFr.84.

Chemistry

BRUNDLE, C. R., and BAKER, A. D. (edited by). Electron Spectroscopy: Theory, Techniques and Applications, Vol. 1. Pp.xv+459. ISBN-0-12-137801-2. (London and New York: Academic Press, a Subsidiary of Harcourt Brace Jovanovich, Publishers, 1977.) £24; $46.90.

CHANG, Raymond. Physical Chemistry with Applications to Biological Systems. p.viii+538. ISBN-0-02-321020-6. (New York: Macmillan Publishing Co., Inc.; ondon: Collier Macmillan Publishers, 1977.) £6.75.

ELIAS, Hans-Georg. Macromolecules. Vol. 1: Structure and Properties. Translated from German by John W. Stafford. Pp.lxxx+532. ISBN-0-471-99487-1. (London and New York: John Wiley and Sons, 1977.) £24; $42.50.

GOODISMAN, J. Contemporary Quantum Chemistry: An Introduction. Pp.x+376. ISBN-0-306-20023-6. A Plenum/Rosetta Edition. (New York: Plenum Publishing Corporation, 1977.) $12.50.

GREENWOOD, N. N., and ROSS, E. J. F. Index of Vibrational Spectra of Inorganic and Organometallic Compounds, Vol. 3 (1964-1966). Pp.1600. ISBN-0-408-70791-7. (London and Boston, Mass.: Butterworths, 1977.) £55.

JONES, R. Alan, and BEAN, Gerritt P. The Chemistry of Pyrroles. (Organic Chemistry: a Series of Monographs, Vol. 34.) Pp.ix+525. ISBN-0-12-389840-4. (London and New York: Academic Press, a Subsidiary of Harcourt Brace Jovanovich, Publishers, 1977.) £21; $41.

LONG, D. A. Raman Spectroscopy. Pp. xiii+276. ISBN-0-07-038675-7. (New York and London: McGraw-Hill International Book Company, 1977.) £14.40.

RAYMOND, Kenneth N. (edited by). Bioinorganic Chemistry—II. (A Symposium co-sponsored by the Division of Inorganic Chemistry and by the Division of Biological Chemistry at the 171st Meeting of the American Chemical Society, New York, N.Y., April 7-9, 1976. Advances in Chemistry Series, Vol. 162.) Pp.viii+448. ISBN-0-8412-0359-8. (Washington, DC: American Chemical Society, 1977.) $14.50.

WALLWORK, S. C., and GRANT, D. J. W. Physical Chemistry for Students of Pharmacy and Biology. Third edition. Pp.xiv+607. ISBN-0-582-44254-0. (London and New York: Longman, 1977.) £7.95.

WANNINEN, Erkki (editor-in-chief). Essays on Analytical Chemistry. (In Memory of Professor Anders Ringbom.) Pp.xiv+607. ISBN-0-08-021596-3. (Oxford and New York: Pergamon Press, 1977.) £27.50.

SAMMES, P. G. (edited by). Topics in Antibiotic Chemistry. Vol. 1: Aminogl Ycosides and Ansamycins. Pp.217. ISBN-85312-059-5. (Chichester: Ellis Horwood, Ltd., 1977. Distributed by Halsted Press, a Division of John Wiley and Sons, Inc., New York, London, Sydney and Toronto.) £12.50; $23.75.

Technology

BECKER, Robert S. The Data Processing Security Game: Safeguarding Against the Real Dangers of Computer Abuse. Pp.103. ISBN-0-08-021790-7. (Oxford and New York: Pergamon Press, 1977.) £3.25.

BURRELLS, W. Microscope Technique: a Comprehensive Handbook for General and Applied Microscopy. Pp.xi+574. ISBN-0-85242-511-2. (Watford, Herts: Fountain Press, Ltd.; Argus Books, Ltd., 1977.) £10.

COULSTON, Frederick, and MRAK, Emil (edited by). Water Quality: Proceedings of an International Forum. (Ecotoxicology and Environmental Quality, Vol. 1.) Pp.xiii+295. ISBN-0-12-193150-1. (New York and London: Academic Press, a Subsidiary of Harcourt Brace Jovanovich, Publishers, 1977.) $14.50; £10.30.

DAHLMAN, Ola, and ISRAELSON, Hans. Monitoring Underground Nuclear Explosions. Pp.x+440. ISBN-0-444-41604-8. (Amsterdam, Oxford and New York: Elsevier Scientific Publishing Company, 1977.) Dfl.120; $49.

DOWSON, D., and HIGGINSON, G. R. Elasto-Hydrodynamic Lubrication. Chapters 9 and 10 by J. F. Archard and A. W. Crook. SI Edition. (Pergamon International Library of Science, Technology, Engineering and Social Studies.) Pp.xiv+235. ISBN-0-08-021302-2. (Oxford and New York: Pergamon Press, 1977.) Hardcover £6.50; Flexicover £3.75.

FARMER, F. R. (edited by). Nuclear Reactor Safety. (Nuclear Science and Technology: a Series of Monographs and Textbooks, Vol .12.) Pp.xiv+216. ISBN-0-12-249350-8. (New York and London: Academic Press, a Subsidiary of Harcourt Brace Jovanovich, Publishers, 1977.) $17.50; £12.40.

GARNELL, P., and EAST, D. J. Guided Weapon Control Systems. Pp.viii+282. ISBN-0-08-019691-8. (Oxford and New York: Pergamon Press, 1977.) £7.50.

HOYLE, Fred. Energy or Extinction?: The Case for Nuclear Energy. Pp.vii+81. ISBN-0-435-54430-6. (London: Heinemann Educational Books, Ltd., 1977.) £1.50 net.

KASPERSON, Roger, and KASPERSON, Jeanne X. (edited by). Water Re-Use and the Cities. Pp.xiii+238. ISBN-0-87451-125-9. (Hanover, New Hampshire: The University Press of New England, 1977. Published for Clark University Press.) $17.50.

KAZAN, B. (edited by). Advances in Image Pickup and Display, Vol. 3. Pp.xiii+302. ISBN-0-12-022103-9. (New York and London: Academic Press, a Subsidiary of Harcourt Brace Jovanovich, Publishers, 1977.) $31; £22.

KLINGER, A., FU, K. S., and KUNII, T. L. (edited by). Data Structures, Computer Graphics, and Pattern Recognition. Pp.xii+498. ISBN-0-12-415050-0. (New York and London: Academic Press, a Subsidiary of Harcourt Brace Jovanovich, Publishers, 1977.) $23; £16.35.

ROSTOKER, William, and DVORAK, James R. Interpretation of Metallographic Structures. Second edition. Pp.xii+250. ISBN-0-12-598260-7. (New York and London: Academic Press, a Subsidiary of Harcourt Brace Jovanovich, Publishers 1977.) $24.50; £17.40.

STRELETS, Kh. L. Electrolytic Production of Magnesium. Translated from Russian. Pp.x+325. ISBN-0-7065-1567-6. (Jerusalem: Israel Program for Scientific Translations; Chichester: John Wiley and Sons, Ltd., 1977.) £24.80; $40.70.

WAKEFIELD, Ernest Q. The Consumer's Electric Car. Pp.xiv+136. ISBN-0-250-40155-X. (Ann Arbor, Michigan: Ann Arbor Science Publishers, Inc.; Chichester: John Wiley and Sons, Ltd., 1977.) $10.95; £6.65.

Earth Sciences

CHANG, Julius (edited by). General Circulation Models of the Atmosphere. (Methods in Computational Physics, Vol. 17.) Pp.ix+337. ISBN-0-12460817. (New York and London: Academic Press, a Subsidiary of Harcourt Brace Jovanovich, Publishers, 1977.) $35.50; £23.20.

HALLAM, A. (edited by). Patterns of Evolution as Illustrated by the Fossil Record. (Developments in Palaeontology and Stratigraphy, 5.) Pp.xiii+591. ISBN-0-444-41495-9. (Amsterdam, Oxford and New York: Elsevier Scientific Publishing Company, 1977.) Dfl.170; $69.50.

HEWINGS, Geoffrey J. D. Regional Industrial Analysis and Development. (The Field of Geography.) Pp.180. ISBN-0-416-75870-3. (London: Methuen and Co., Ltd., 1977.) £3.25 net.

PEEL, R. F., CURTIS, L. F., and BARRETT, E. C. (edited by). Remote Sensing of the Terrestrial Environment. (Proceedings of the Twenty-eighth Symposium of the Colston Research Society, held in the University of Bristol, April 5th to 9th, 1976.) Pp.xvii+275. ISBN-0-408-70805-0. (London and Boston, Mass.: Butterworths, 1977.) £12.

SALOP, L. F. Precambrian of the Northern Hemisphere and General Features of Early Geological Evolution. (Developments in Palaeontology and Stratigraphy, 3.) Pp.ix+378. ISBN-0-444-41510-6. (Amsterdam, Oxford and New York: Elsevier Scientific Publishing Company, 1977.) Dfl.145; $59.25.

SORREL, Charles A., and SANDSTROM, George F. The Rocks and Minerals of the World. Original Project Editor: Herbert S. Zimm. Pp.288. ISBN-0-00-21982-4. (London and Glasgow: William Collins Sons and Co. Ltd., 1977.) Hardback £3.95; Paperback £2.50.

SULAKVELIDZE, G. K., GLUSHKOVA, N. I., and FEDCHENKO, L. M. Forecasting of Hail, Thunderstorms and Showers. Translated from Russian. Pp.ix+150. ISBN-0-7065-1569-2. (Jerusalem: Israel Program for Scientific Translations; Chichester: John Wiley and Sons, Ltd., 1977.) £11.75; $19.25.

WHITAKER, J. H. McD. A Guide to the Geology Around Steinsfjord, Ringerike. Pp.56. ISBN-82-00-05013-0. (Oslo, Bergen and Tromsø: Universitetsforlaget, 1977. Distributed in UK by Global Book Resources, Ltd., Henley on Thames, Oxon.) N.kr.39.50; $8.

YELLEN, John E. Archaeological Approaches to the Present: Models for Reconstructing the Past. (Studies in Archaeology.) Pp.xvi-259. ISBN-0-12-770350-0. (New York and London: Academic Press, a Subsidiary of Harcourt Brace Jovanovich, Publishers, 1977.) $24; £17.05.

Biology

ADVANCES OF QUANTITATIVE IMAGE ANALYSIS; QUANTITATIVE IMAGE ANALYSIS OF BIOLOGICAL STRUCTURES. (*Microscopica Acta:* Journal of Microscopic Equipment, Methods and Applications, Supplement 1.) Pp.221. ISBN-3-7776-0330-9. (Stuttgart: S. Hirzel Verlaf, 1977.) DM45.

ALEXANDER, Martin. Introduction to Soil Microbiology. Second edition. Pp.xi+467. ISBN-0-471-02179-2. (New York and London: John Wiley and Sons, 1977.) $23; £13.50.

AW, S. E. Chemical Evolution: An Examination of Current Ideas. Pp.155. (Singapore: University Education Press, P.O. Box 96, 1976.) Hardcover US$12; Softcover US$5.

BARBOUR, Michael G., and **MAJOR**, Jack (edited by). Terrestrial Vegetation of California. Pp.ix+1002. ISBN-0-471-56536-9. (New York and London: Wiley-Interscience, John Wiley and Sons, 1977.) $60; £35.65.

BOWMAN, John C. Animals for Man. (The Institute of Biology's Studies in Biology, No. 78.) Pp.69. ISBN-0-7131-26299. (London: Edward Arnold (Publishers), Ltd., 1977.) Boards £3.20; Paper £1.60.

CARTER, C. O. Human Heredity. Second edition. Pp.286+4 plates. (Harmondsworth, Middlesex: Penguin Books, Ltd., 1977.) £1.25.

CHEVALLIER, F. Biodynamics and Indicators. Pp.xiv+225. Translated from the French by E. Drucker. ISBN-0-677-30440-4. (New York, London and Paris; Gordon and Breach Science Publishers, 1977.) £13.

DIMBLEBY, Geoffrey W. Ecology and Archaeology. (The Institute of Biology's Studies in Biology, No. 77.) Pp.54. ISBN-0-7131-2632-9. (London: Edward Arnold (Publishers), Ltd., 1977.) Boards £3; Paper £1.50.

EDWARDS, C. A., and **LOFTY**, J. R. Biology of Earthworms. Pp.xviii+333. Second edition. ISBN-0-470-99147-X. (London: Chapman and Hall, 1977. Distributed in the USA by Halsted Press, 9 Division of John Wiley and Sons, Inc., New York.) Paperback £4.25; Hardback £8.

GRASSE, P. P. Larousse Animal Portraits. Consultant Editor: Dr. Maurice Burton. Pp.175. ISBN-0-88332-076-2. (London, New York, Sydney and Toronto: Hamlyn, 1977.) £6.95.

GWATKIN, Ralph B. L. Fertilization Mechanisms in Man and Mammals. Pp.x+161. ISBN-0-306-31009-0. (New York and London: Plenum Press, 1977.) $21.

HILL, Terrell L. Free Energy Transduction in Biology: The Steady-State Kinetic and Thermodynamic Formalism. Pp.xii+229. ISBN-0-12-348250-X. (New York and London: Academic Press, a Subsidiary of Harcourt Brace Jovanovich, Publishers, 1977.) $21; £14.90.

HILL, Thomas A. The Biology of Weeds. (The Institute of Biology's Studies in Biology, No. 79.) Pp.64. ISBN-0-7131-2637-X. (London: Edward Arnold (Publishers), Ltd., 1977.) Boards £3; Paper £1.50.

KUCHLER, Robert J. Biochemical Methods in Cell Culture and Virology. Pp.ix+331. ISBN-0-470-99043-0. (Stroudsburg, Pennsylvania: Dowden, Hutchinson and Ross, Inc., 1977. Distributed by Halsted Press, a Division of John Wiley and Sons, New York and Chichester.) $38; £22.50.
